DR. ALEXANDER MCPHEDRAN, Toronto: The universal tendency is to regard the phenomena following a cause as resulting from that cause. To nothing does this apply more fully than to therapeutics. The wish is too often father to the thought. The masses are still imbued with the ancient belief in the mythical power of drugs, and relatively the profession often shows quite as blind a faith. Dr. McPhedran urges that in estimating the effect of our therapeutic measures we should more carefully consider the natural or uninfluenced course of disease. He calls attention to the many variations which may occur in the natural course of all diseases, and how readily they can be erroneously ascribed to the administration of drugs. He emphasizes this by reference to pernicious anemia and its treatment by arsenious acid to typhoid fever, diseases of the heart, neuropathic affections, and tuberculosis. It is essential that a careful record of the patient's condition be made, with variations in the course of the illness, in order to enable us to direct intelligently the treatment and accurately estimate its effect. With the advent of the laboratory the tendency has been to rely upon it to the neglect of the proper study of the patient himself. The paper closes with a plea for the more careful keeping of hospital records.

DISCUSSION.

DR. B. E. MCKENZIE, Toronto, emphasized the importance of accurate observation of the patient in order that the physician may know the causes which produce definite results. Too often the results are *post hoc* rather than *propter hoc*, and a careful study of the patient would have shown that the changes ascribed to drugs were but natural variations in the course of the disease. He illustrated this by reference to anterior poliomyelitis.

DR. THOMAS E. SATTERTHWAITE, New York, spoke first of intestinal antisepsis. We must distinguish between drugs that kill and those that inhibit the development of bacteria in the intestine. He believed that Dr. McPhedran would agree with him that certain drugs, like the mercurials, do exert an inhibitive action, and to this extent they are intestinal antiseptics. He told a story of Alonzo Clark to illustrate how the most eminent physician can be deceived as to the outcome of heart lesions. Speaking of tuberculosis, he said that when the specific bacillus was discovered the pathologists believed that the cure of the disease was at hand. The claims made then have not been made good, and now the laity is trying to force the profession into the unnatural position of producing a cure when it cannot do so. It is true that medicine is not an exact science; neither is chemistry. He commended the suggestion as to reform in the keeping of hospital records. In a hospital with which he is connected each patient on entering is examined from head to foot, and the results are noted and handed to the superintendent without diagnosis. Then the staff meets, the reports are considered, and after discussion a general vote is taken as to the diagnosis.

DR. OLIVER T. OSBORNE, New Haven, said that the Connecticut State Hospital for the Insane has used this method for years. He believed that we can secure some degree of asepsis of the upper intestinal tract. What disease can we treat without first cleaning out the bowel to see what symptoms are left? Cleanliness is next to asepsis, but we can do more than secure mere cleanliness. He emphasized the point by reference to salol and its fate in the bowel.

DR. FRANCIS M. POTTENGER, Los Angeles: It is true that we are losing sight of the importance of accurate observation of the patient, and improved laboratory methods have tended to bring about this result. Too often we draw our conclusions wholly from the results of examination of the blood, urine, or stomach contents. No class of patients has suffered more in this way than tubercular patients. Tuberculosis is suffering not from too much laity but from too little doctor, — not enough professional study. Ordinarily the physician does not take sufficient interest in these cases. It should be remembered that the disease is curable in its early stages.

DR. A. D. BLACKADER, Montreal, said that the early physicians were too optimistic, their followers were over-skeptical, and now we are upon the middle ground, pharmacology having taught us just what drugs can do. He only can use remedies effectively who understands their action and understands thoroughly the case before him. A stock broker had said that he felt successful if 51% of his ventures resulted favorably; and so with medicine, — we should be encouraged if we get 51% of benefit.

DR. H. C. WOOD, Philadelphia: Medicine is an art, not a science. It is an art founded on science. So is music. The composer must know something of the science of acoustics in order that he may know the art of music. So with medicine; the physician, in order to reach a point of eminence, must know the facts of science upon which his art is based. Pharmacology, for

instance, is a science, — an exact science. The successful practitioner is an artist in the highest sense.

Dr. Robert Reyburn, Washington, said that the young physicians of to-day are not so well able to care for their patients as the older practitioners. They have a greater technical knowledge, but lack the ability to look after their patient's welfare. He was in favor of the old-time preceptor; thus students were enabled to see as well as to hear. Increase the sphere of clinical observation; study the patient rather than his disease.

Dr. Louis Kolipinski, Washington, said that the conception that medicine is a science probably originated with some one outside of the profession. Whether it is or is not does not help our patients. He agreed with all that had been said as to the importance of closer clinical observation.

Dr. McPhedran, in closing, further emphasized the necessity for closer observation and better records. Science is knowledge; we know certain facts relating to medicine and so are scientists; in this sense medicine is a science. He was not convinced as to the value of intestinal antisepsis and had no faith in salol; typhoid is a constitutional disease, not a local bowel trouble. He knew no cure for it.

THE TREATMENT OF POST-PARTUM PUERPERAL ECLAMPSIA.

Dr. D. Olin Leech, Washington: Post-partum eclampsia differs from the ante-partum form. The mortality in the former is less. Treatment consists in the arrest of convulsions and elimination of the poison. Morphine in ½ gr. doses is the best remedy to stop the convulsions. Chloroform may be administered, and chloral per rectum is helpful. He highly commends tincture of veratrum viride in 10 to 20 minim doses until the pulse rate falls to 60. It acts like venesection. The poison should be eliminated through the kidneys, bowels and skin. The bowels should be emptied by repeated enemata, and this followed by a pint of salt solution. Hypodermoclysis may be employed if necessary. Six ounces of milk should be given every two hours, and plenty of water. The potassium diuretics are not advisable. Activity of the skin should be promoted by the use of hot air baths, or hot packs. He has used the former to good advantage. Pilocarpine is not a safe drug to use. Magnesium sulphate or croton oil may be used as cathartics. Basham's mixture and strychnia are the best remedies in the after-treatment. Three cases of post-partum eclampsia are reported.

DISCUSSION.

Dr. H. C. Wood, Philadelphia, spoke of the physiological action of veratrum viride. Recent studies have shown that it is not a vaso-dilator, but the reduction in blood pressure is due to the slowing of the pulse rate. Jervine was formerly believed to be its dominant alkaloid, but it is now known that it plays but a subordinate part. The chief constituent, protoveratrine, is a heart stimulant. Thus veratrum viride is a stimulant rather than a sedative. If it does good in eclampsia it is by bleeding the patient into his own vessels.

Dr. W. M. Sprigg, Washington: The presence or absence of albumin in the urine is not so important a guide as the quantity of urea eliminated. In many cases of eclampsia little or no albumin is present; but deficient elimination of urea is always a danger signal. He believed that the same toxic conditions are present in eclampsia after as before delivery, and the treatment is practically the same except that in the post-partum form the uterus has gotten rid of the placenta, the source of the toxins.

Dr. Robert Reyburn, Washington, agreed with Dr. Sprigg as to the importance of urea elimination as a guide. He advocated venesection in certain cases, and cited an instance in which the removal of 16 oz. of blood from a plethoric woman was followed by almost marvelous results. The convulsions ceased immediately.

Dr. Philip King Brown, San Francisco, said that the work of Follin has shown that the urea elimination has nothing to do with eclampsia. In a recent article he shows that no matter how great the retention of urea eclampsia does not necessarily follow. Experiments on patients who have previously suffered from eclampsia point to the same conclusion. The only significance is that something else is retained if urea is. He believed that eclampsia is not due to any one cause. For one thing it is probably due to toxins from the placenta. The thyroids may also play a part.

Dr. W. A. Campbell, Colorado Springs, said that he had seen two cases of eclampsia within six months. In both cases the removal of clots from the uterus was followed by cessation of the convulsions.

(To be continued.)

Book Reviews.

Medical Jurisprudence, Forensic Medicine and Toxicology. By R. A. Witthaus, A.M., M.D., Professor of Chemistry, Physics and Toxicology in Cornell University, and Tracy C. Becker, A.B., LL.B., Councillor at Law, Professor of Criminal Law and Medical Jurisprudence in the University of Buffalo, with the collaboration of 19 others. Second edition. Vol. II. Illustrated. Pp. 1008. New York: William Wood & Co. 1907.

We reviewed the first volume of the second edition of this work in our issue of April 11, 1907, and on that occasion made the statement that the book is encyclopedic in character and contains a fund of information which should be of vital interest to physicians in general, and particularly to those whose duties bring them into close relations with courts. This statement applies in equal degree to this second volume, in which the editors have the collaboration of the same writers as in the first volume. This volume contains and continues subjects relating to dead bodies or thanatology, under which is included the consideration of wounds, by gunshot and other means, death by electricity, from mechanical suffocation, from submersion, with a section on the determination of survivorship, The following section of the book concerns itself with biothanatology, or matters relating to both dead and living. Under this heading is taken up questions of abortion and infanticide, various crimes against women, and finally, railway injuries. The book in general will undoubtedly stand as an authoritative statement for many years to come on matters relating to the border line between crime and medicine.

A Text-Book of Practical Therapeutics, with Especial Reference to the Application of Remedial Measures to Disease and Their Employment upon a Rational Basis. By HOBART AMORY HARE, M.D., B.Sc., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia, etc. Twelfth edition, enlarged, thoroughly revised and largely rewritten. Illustrated. Pp. 939. Philadelphia and New York: Lea Brothers & Co. 1907.

The twelfth edition of a book requires no special comment beyond a statement of changes. As a matter of fact, inasmuch as this edition has appeared only eighteen months after its predecessor, comparatively few fundamental changes in treatment have taken place worthy of recording. Among these is the value of citrate of sodium, the treatment of syphilis by hypodermic injection, certain matters relating to saline solutions, citric acid for thrombosis in typhoid fever, and the danger of toxemia after the use of chloroform and ether. Revision has been made of the articles relating to the eye by Dr. G. E. de Schweinitz, and also of certain other articles. Since the eleventh edition the book has been translated into the Italian and Chinese languages. Its value is not to be questioned, but its title, "Practical Therapeutics," is rapidly becoming too comprehensive for the subject matter it contains. It is practically devoted to drug treatment, which must now be regarded merely as a part of therapeutic procedure.

A Laboratory Manual of Invertebrate Zoölogy. By GILMAN A. DREW, Professor of Biology at the University of Maine. 12mo, pp. 201. Philadelphia: W. B. Saunders Co. 1907.

This little volume is of unusual excellence and is perhaps the best of its kind. It is based upon the instructions prepared by Professor Drew and others for the elementary courses given in the Marine Biological Laboratory at Woods Holl. The directions have been in practical use for several years and have been repeatedly revised, under the general supervision of Professor Drew himself, by many of the workers in the laboratory. It contains for each large group of invertebrates a table of classification, with admirable succinct definitions of the principal divisions, which are so good that they alone would suffice to make the book valuable. For each group a number of characteristic forms have been selected and concise directions drawn up for their laboratory study. These are cleverly designed so as to guide the student sufficiently and yet force him to use his own powers of observation. At the end of the book is a glossary occupying 14 pages, the definitions of which have been formulated with a skill which one wishes were more common with dictionary makers. The little volume will probably be widely used for elementary zoölogical instruction.

The Essentials of Histology. By E. A. SCHAEFER. Seventh edit on. Philadelphia: Lea Bros. & Co. 1907.

The mere fact of the appearance of the seventh edition of this text-book is evidence of the great and steady favor with which it has been received. It is, indeed, a most excellent work, and the improvements which have been made for the present edition are numerous and important. We find many of the most recent investigations adequately heeded, so that information is here presented not yet in other text-books, being elsewhere recorded only in original memoirs. We find this to be the case with spermatogenesis, sinusoids, and especially with regard to the nervous system, of which the investigations of Golgi, Cajal, Apathy and many others have greatly widened our information. Although the book has grown greatly in size, it is still a slim volume, owing to the use of an excellent thin paper on which the illustrations are very successfully printed. Many of them have been improved by the use of colored inks, imparting a much greater resemblance to the actual preparations.

The author's presentation of the subject is clear and felicitous, the more important facts being emphasized, and padding with unimportant details being conscientiously avoided throughout. As a compact book of reference and as a first-class medical text-book this publication may be cordially recommended.

Modern Surgery, General and Operative. By JOHN CHALMERS DA COSTA, M.D., Professor of the Principles of Surgery and of Clincal Surgery, Jefferson Medical College; Surgeon to the Philadelphia Hospital, and Consulting Surgeon to St. Joseph's Hospital, Philadelphia. Fifth edition, thoroughly revised and enlarged, with 872 illustrations, some of them in colors. Philadelphia and London: W. B. Saunders Co. 1907.

Professor Da Costa's fifth edition has been a great solace to this reviewer. It is the work of a trained teacher whose productions become more popular with time. Fifteen years have passed since Da Costa published the first modest edition of his Manual, as he then called the book, a piece of writing which forms the foundation merely of the present work. The author aims to keep his readers abreast of the times, and has incorporated in every succeeding edition the latest surgical knowledge. For instance, in the fifth edition, which covers 1,283 pages of close printing, there are additional essays on bone lesions, on infections, on Harvey Cushing's most recent work on the head, on Ransohoff's operation for empyema, and on Brophy's for cleft palate; on the opsonins, on new methods of anesthesia, on advanced operations for breast cancer, on Hugh Young's prostatectomy, on Moynihan's and the Mayos' contributions to gastro-intestinal surgery, on Matas's operation for aneurism, and on dozens of other new and interesting topics.

We commend the book, as we have previously commended it, to surgeons and to students as the most satisfactory one-volume contemporaneous treatise on surgery, published in this country.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, NOVEMBER 7, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 Boylston Street, Boston, Mass.

MEDICAL BOOKS AND BOOK REVIEWS.

It is commonly said, and often rather thoughtlessly, that too many medical books are written and that in many departments of medicine there is no present need of further additions. It should be remembered by such critics that many books must always be written before one of marked superiority emerges to be generally accepted as authoritative. It is true of medical books as of other departments of human endeavor that there is room at the top and comparatively little anywhere below. The natural result is that many medical men endowed with a legitimate amount of self-confidence believe that they are capable of presenting a subject in a more attractive or a more conclusive form than has hitherto been the case. This attitude of mind is certainly salutary, and, in fact, indispensable to progress. If prospective writers of medical books were to abstain from the effort to put their ideas into words for the benefit of others, through modesty or the recognition that other books had been written on the same subject, it is not likely that the need, which now and always has existed, of excellent text-books would be met. A far safer course of action is to encourage by all legitimate means the writing of books in the hope that from the mass of possible mediocrity an occasional work of real significance, either from the didactic or the research point of view, will emerge. The competition among books is just as healthy a tendency as that in the industries in general. It would be altogether unfortunate if certain men or groups of men wrote all the books and were regarded as having a right to dictate to the rest of the medical profession in this regard. With the general and widespread competition which now exists, it is perfectly evident that the good books and those which are useful, whether to students or to men already in practice, will survive, whereas the others will sink into oblivion, which many of them very possibly deserve. The process at least is a natural one, and one which certainly should not be discouraged by the continued assertion that we have too many books and that the same ground is covered again and again.

An analysis of the reviews of medical books, appearing in medical journals, is also of interest. It is to be remembered that under the influence of modern specialization books in any one department of medicine are ordinarily reviewed by experts in those departments, men for whom the book under consideration may present nothing new, and to whom it very naturally appears commonplace and unnecessary. The object of the ordinary text-book, however, is not to appeal to specialists, but rather to present special subjects in a form accessible to and readable by practitioners in other departments of medicine. It is, therefore, absurd for a reviewer of a book, for example, on the eye, or the ear, or internal medicine, to assert that the volume is unnecessary and not needed simply because it reiterates what he already knows and what, in fact, may be common knowledge of those versed in that particular branch of medicine. Such criticism is both superficial and meaningless. What the critic of such a book should determine is whether it presents knowledge in a systematic fashion, with accuracy, and in a manner to appeal to the ordinary reader. These are the qualities which justify the production of new books, however much the subjects may have been traversed before and however elementary they appear. As medicine develops and subdivides, there is evidently increasing need for simple and succinct statements of well recognized facts. It is proverbial and certainly true that to write a concise book on any subject is a far more difficult task than to elaborate a monograph. Selection is a peculiarly difficult task, and one which should always be commended, if well done.

These points book reviewers in general frequently overlook. We have sometimes thought that it might be well if three quarters of the medical books were sent for review to those who in the future are going to use them. There is no question that the estimate of a book at the hands of an expert in the subject under consideration would be far different from that of a practitioner who in the endless details of his practice is eager

for a clear and even commonplace presentation of the subject. Much illiberality in the reviewing of books is apparent. They are dismissed often with a few words and with insistence on the fact that they are superfluous. It would be well to recognize the palpable fact that what is superfluous for one man is a necessity for another, and that many text-books are good just in proportion to the number of physicians they benefit. For our part we welcome new books, recognizing that some of them are excellent and most of them useful. We are strongly disinclined to condemn a book simply because it is a repetition of what has already been said. On the contrary, every encouragement should be offered to writers of books in the hope that ultimately results will appear which could be obtained by no means requiring less active competition.

PROFESSOR JOSEPH LEIDY.

A STATUE of Prof. Joseph Leidy was unveiled Wednesday, Oct. 30, 1907, at the City Hall Plaza, Philadelphia. This occasion, commemorating as it did the services of one of the greatest scientists which this country has produced, should not be allowed to pass unnoticed. At a time when the people of the country were mainly employed in other occupations than the development of science, Leidy rapidly rose into prominence and became widely known in these fields outside of his native city.

Born in Philadelphia, Sept. 29, 1823, Leidy was graduated from the University of Pennsylvania with the degree of doctor of medicine in 1844. In 1845 he became prosector to the chair of anatomy in the University of Pennsylvania, occupied at that time by Dr. Horner. The following year he was demonstrator of anatomy at the Franklin Medical College. In 1852 he took Dr. Horner's place as professor of anatomy in the University of Pennsylvania, and a year later, on the death of Dr. Horner, was made full professor of anatomy at that institution. He was then thirty years of age. In 1871 his interests were extended by the appointment to the professorship of natural history in Swarthmore College. In 1884 he became director of the Department of Biology at the University of Pennsylvania. Among the many honors which were conferred upon him, both here and abroad, were the Walker Prize from the Boston Society of Natural History, and the Lyell Medal from the London Geological Society in recognition of valuable contributions to paleontology. He was a member of the Royal Microscopical and Geological Society of London, of the Paris Academy of Science and of an immense number of other similar bodies. In 1886 he received the degree of doctor of laws from Harvard University. He died in 1891.

Leidy was, perhaps, better known as a naturalist than as an anatomist, or at least as a human anatomist. His contributions to comparative anatomy, botany, mineralogy, geology, microscopic zoölogy, helminthology, and especially to paleontology, were numerous and of great value. One of his notable discoveries of a highly practical sort was that the hog is the host from which the trichina is introduced into the human system. Leidy occupied in Philadelphia somewhat the same position that Dr. Jeffries Wyman held in Boston.

A statue to Leidy, such as now graces one of Philadelphia's public places, is a just mark of the appreciation in which he is held by his native city as well as by the world at large. The statue stands on a pedestal of granite some eight feet in height and is of bronze. The figure is standing and in an attitude of explanation. A feature which will strike the casual observer is the fact that he is represented in a sack coat instead of a more conventional garment out of deference, it is said, to his custom of never wearing any other sort of coat.

The statue was presented to the city by Mr. Talcott Williams, representing Mr. Joseph Wharton, chairman of the Memorial Committee; in his remarks he compared the attainments of Leidy to those of Stephen Girard and Benjamin Franklin. Mr. Wharton, arriving later, spoke further of Leidy's extraordinary achievements and of his lovable character. The main address was made by Dr. Henry C. Chapman, representing the Academy of Natural Sciences. Dr. Chapman characterized Leidy as "the greatest naturalist this and possibly any other country ever produced," and gave a sympathetic and appreciative estimate of his service to anatomy and to the sciences in general. The vice-provost of the University of Pennsylvania, Prof. Edgar F. Smith, president of the American Philosophical Society, supplemented Dr. Chapman's remarks. Representatives of many institutions of learning were present as well as a large number of invited guests. Among these was Professor Leidy's widow. The country at large should share with Philadelphia the satisfaction it must feel in having publicly recognized the services of this pioneer in the natural sciences.

MEDICAL NOTES.

Mr. Horace Fletcher on Muscular Efficiency after Fifty without Exercise. — A public lecture is announced at the New York Academy of Medicine for Thursday, Nov. 14, by Mr. Horace Fletcher, on the subject, "Possible Progressive Growth in Muscular Efficiency after Fifty Years of Life without Systematic Physical Exercise."

A New College of Medicine. — It is announced that the University of Wisconsin has organized a college of medicine at which, for the present, the first two years only of the medical course will be given. Requirements for entrance are at least two years of college work, with specific requirements in Latin, French, Germany, physics, chemistry and biology. The dean is Dr. C. R. Bardeen.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Nov. 6, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 55, scarlatina 46, typhoid fever 8, measles 14, tuberculosis 47, smallpox 0.

The death-rate of the reported deaths for the week ending Nov. 6, 1907, was 19.42.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Nov. 2, 1907, was 244, against 210 the corresponding week of last year, showing an increase of 34 deaths and making the death-rate for the week 20.88. Of this number 130 were males and 114 were females; 240 were white and 4 colored; 134 were born in the United States, 100 in foreign countries and 10 unknown; 47 were of American parentage, 166 of foreign parentage and 31 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 56 cases and 4 deaths; scarlatina, 41 cases and 0 deaths; typhoid fever, 10 cases and 2 deaths; measles, 12 cases and 0 deaths; tuberculosis, 47 cases and 28 deaths; smallpox, 0 case and 0 deaths. The deaths from pneumonia were 26, whooping cough 0, heart disease 24, bronchitis 5 and marasmus 6. There were 26 deaths from violent causes. The number of children who died under one year was 47; the number under five years, 59. The number of persons who died over sixty years of age was 59. The deaths in public institutions were 82.

There were 1 case and 2 deaths reported from cerebrospinal meningitis during the week.

Meeting of Health Boards. — At a recent meeting of the Massachusetts associations of Boards of Health, at which Dr. Henry P. Walcott, chairman of the State Board of Health, presided, papers were read by Prof. James O. Jordan, milk inspector in the Boston Health Department, and by Dr. E. Channing Stowell, on the Possibilities of a Clinical Laboratory in Country Towns in Relation to Public Health Work.

NEW YORK.

Budget for Department of Health. — The city budget for 1908 was finally determined upon by the Board of Estimate and Apportionment on Oct. 30. The amount allotted to the Department of Health is $2,279,499, an increase of $432,029 over its appropriation for the present year. Of this increase, it is stated by the municipal authorities that $375,000 is mandatory, being required to maintain the existing plant at its present level of efficiency, and to provide for the completion and equipment of the city tuberculosis sanitarium at Otisville, Orange County. The only item in the increased appropriation which may be considered as optional and not absolutely required, either by law or to prevent deterioration in departmental work, is $35,000 for milk extension and an increased force for the department.

Obituary.

RESOLUTIONS ON THE DEATH OF RICHARD HENRY DERBY, M.D.

The Board of Directors and the Board of Surgeons of the New York Eye and Ear Infirmary record with profound regret the death of their late associate and colleague, Dr. Richard Henry Derby.

Dr. Derby was born in Boston in 1844; was graduated from Harvard in 1864, and from the Harvard Medical School three years later. He served as house surgeon in the Massachusetts General Hospital and subsequently went to Germany to further his studies. He was a pupil of the distinguished German ophthalmologist, Professor Von Graefe, and acted as his assistant during his stay abroad. In 1870 he returned to America and settled in New York.

Dr. Derby was appointed clinical assistant in the New York Eye and Ear Infirmary in 1871, assistant surgeon in 1873 and surgeon in 1874, and up to the time of his death was a member of our staff.

In 1886 he was elected a regular member of the Board of Directors, although he had been a member, *ex-officio*, since 1876, as well as a secretary of the Board for three years. Upon the resig-

nation of Dr. Noyes as executive surgeon, Dr. Derby was appointed as his successor, which position he held until the time of his decease, which occurred July 4, 1907. He was always deeply interested in the affairs of the institution, and for many years was a member of the executive committee.

At the time of his death Dr. Derby was a member of the New York Academy of Medicine and the American Ophthalmological Society; was a trustee of the New York Institution for the Blind, and was connected with the New York Orthopedic Dispensary and Hospital and Trinity Hospital as consulting ophthalmologist.

He was a man of great public spirit and prominent in many of the civic movements of his times; was a member of the council of the Charity Organization Society and the State Charities Aid Association; was one of Commissioner Waring's aids; an unpaid health inspector in the service of the Health Department and a member of the Committee of Seventy in 1894 and the Committee of Twenty-one in 1881 which met to reform the street cleaning system. He was also a vestryman in Trinity Church.

Dr. Derby's wide experience as ophthalmologist, his genial manner, as well as his staunch integrity, gained for him the respect and esteem of all with whom he came into contact whether professionally or socially, and his loss will continue to be deeply felt.

Resolved, That these resolutions be spread upon the minutes and that a copy be sent to the family of the deceased.

JAMES J. HIGGINSON, *Chairman*,
NEWBOLD MORRIS,
CHARLES STEDMAN BULL,
GORHAM BACON,
WALTER EYRE LAMBERT,
Joint Committee.

2. TAYLOR, R. W. *Syphilis and Massage.*
3. WILLSON, R. N. *The Presence in Vaccine Virus of Bacilli and Spores Resembling Those of Tetanus.*
4. WINSTON, J. W. *Management of the Third Stage of Labor.*
5. JACKSON, C. *Septal Perforations: Their Closure by Plastic Operations.*
6. LEWIS, D. *Practical Venereal Prophylaxis.*

1. Abbe has made use of radium emanations in numerous cases, and has found it of great value and its action entirely different from that of the x-rays, or electricity. The author believes that radium ranks with the specifics. It is a specific for erratic cell growth. Details of its use are not yet fully worked out, and the dosage is still empirical. Some apparent cures of epitheliomata and sarcomata have endured for three years already. The force exerted by radium is in part an electric discharge, essentially of negative elements. Possibly it may supply an electric force vital to normal and orderly growth, the loss of which causes the formation of tumors. It is supplementary to x-rays and does good where they fail. The overaction of strong radium is injurious. The best results have followed one hour's exhibition of 10 mgr. R. B. on small growths, and four hours on larger ones. Ischemia of the parts aids the effect. Pigmented moles, melanotic growths and giant-celled sarcoma are particularly benefited by it. Its value in nevi and angiomata is due to its irritant action producing obliterative endarteritis and fibroid changes.

8. WITHERBEE, W. D. *The "Open Method" Treatment of Cancer.*

3. In the second part of his article the writer discusses the mortality from tuberculosis among the Jews, Irish and negroes, and the relative mortality of city and country dwellers. His conclusions are: (1) races during the process of citification acquire an appreciable degree of immunity to, or increased resistance against, tuberculosis; (2) different classes of the same race appear to acquire varying degrees of a similar immunity; (3) estimation of these facts may help prognosis; (4) in the fight against tuberculosis one at least of the great forces of nature is helping, as seen in the remarkable increase of resisting power represented in the contrast in the mortality from tuberculosis of 2,488 per 100,000 in the Sioux Indians and of 71 per 100,000 in the Polish Jews. [R. I. L.]

1. Barker reviews the various symptoms of exophthalmic goiter. Pycnocardia, as he prefers to call tachycardia, is the most constant and most important sign. In doubtful cases it may be brought out by a few doses of thyroid tablets. Enlargement of the thyroid gland is present in most cases when carefully looked for. It is as a rule slight and of vascular character. Exophthalmos is entirely absent in one third of the cases and is usually late. The various other eye signs may be of value in early cases, when perhaps only tachycardia is present. Tremor and the other thyreotoxic, neuropathic and psychopathic phenomena indicate a well developed disease. Barker, an internist, thinks it the duty and privilege of the physician to recommend early operation in this disease.

2. Preble divides the medical treatment of exophthalmic

goiter into two categories: (1) correction of the neurosis and (2) counteraction of the perversion of thyroid secretion. Rest and general hygienic and dietetic measures are apparently of some use in certain cases. Drugs, as iron, bromides, bromide of quinine, iodides, etc., seem to have no direct effect. The various organic preparations are useless with the exception of that from the thyroid itself, which is positively harmful. The various antitoxic and cytotoxic preparations, manufactured to combat the thyroid secretion, seem of very little value. Yet in spite of this discouraging review of medical treatment, the writer is inclined to advise general medical treatment, largely rest and hygiene, but only as long as the patient does not get worse.

3. Kocher urges great conservatism in the operative treatment of exophthalmic goiter. Operation is contraindicated in the time of severe intoxication. This is determined by the intensity of the various symptoms and the blood examination. It has been found that the lymphocytes increase with the progress of the disease. At the time of severe intoxication he advises medical treatment, rest and cytotoxic serum. The experience of the writer and his father has taught them to prefer several operations rather than a single extensive one. More than two arteries are never ligated at a sitting. Removal of more than one lobe of the gland at a time is dangerous. Bleeding and injury to the portion of the gland left are carefully avoided. The object of these operations is to reduce the diseased tissue or its increased vascularization and thereby reduce the absorption of thyroid secretion. In 315 operations on 254 patients with exophthalmic goiter the writer reports a cure in 83%, with a total mortality of 3.5%.

8. Craig uses eserin salicylate in1-40 gr. doses subcutaneously at the time of operation as a prophylaxis against post-operative intestinal paresis. He reports three cases of its use in the cure of this condition when it had not been used in the prophylactic manner. [R. I. L.]

2. Newell reports marked benefit from the use of scopolamine-morphine anesthesia in obstetrics; no bad effects noted. The solution was used as follows: as soon as uterine contraction occurred, at five-minute intervals an initial dose containing 1-150 gr. scopolamine, and ¼ gr. of morphine was given hypodermically. This was repeated at intervals of one to two hours, unless patient showed marked reaction to the initial dose. In no case was the dose repeated after the cervix became two thirds dilated. The results of this treatment were that the pain of labor was markedly reduced; the recollection of pain endured was almost obliterated; labor was shortened, as well as made easier; the necessity of operative interference has been distinctly reduced; there has been no tendency to hemorrhage. It is important that the drugs be used as fresh as possible.

3. Fry has reviewed the cases of pubiotomy done in America. He concludes that it is a satisfactory operation for enlarging the pelvic girdle in moderate degrees of contraction. It is easy to perform, and can be employed in small flat pelves. The convalescence, however, is usually unsatisfactory, and the writer feels for this reason it will obtain but a limited field of usefulness as an elective operation. The indications for pubiotomy are a living child and some contra-indications to Cesarian section.

4. King describes a method of version in transverse presentations by the employment of thigh pressure of the mother upon the external surface of the abdomen, induced either by squatting or the kneeling posture. In several instances this method, correctly applied, has been successful in transforming a transverse presentation into one of the vertex.

6. In the prevention of ophthalmia neonatorum, Cragin has used the various silver preparations in varying strengths in a large series of cases. He concludes that the most efficacious salt is 20% argyrol.

15. Peterson reports the treatment of chronic inversion of the uterus. In his opinion the vaginal route and the operation of anterier colpohysterotomy (Spinelli) are much preferable to the abdominal route or other forms of operation; by this means the uterus can be replaced, and several instances of subsequent pregnancy have been observed. The article is well illustrated.

16. After complete removal of the uterus, inversion of the vagina will follow in a considerable portion of all cases, unless while removing uterus stumps, all its ligaments be securely fastened in the fundus of the vagina. Harris reports his method of so fixing the ligaments, and advocates its employment in all cases of total hysterectomy.

9. *Watson, C. *The Influence of Diet on the Liver.*

8. Kenwood, in an article on hygiene as a school subject in elementary schools, believes that if the teaching of the simpler rules of hygiene were spread over the whole school curriculum it would make but little demand upon the time and energy of the teachers, either in acquiring the necessary knowledge or communicating it to the scholars. He believes that such a scheme should embrace the following items: (1) the importance of fresh air and how to obtain it; (2) the importance of cleanliness of person and surroundings; (3) the healthy maintenance of certain bodily functions and the formation of hygienic habits; (4) the

dangers of contamination of water, air and food, and how to guard against them in the home; (5) temperance in all things; (6) for girls, the elementary facts of the care of infants, and the selection of food and simple cooking. In other courses he believes that the subject of hygiene could be indirectly introduced by means of compositions on matters pertaining to hygiene and proper living. He believes that this subject if properly introduced will do much toward improving the physical condition of the students at the school and in their homes.

9. Watson has experimented on rats by feeding certain series meat alone and others a pure carbohydrate diet. He gives the details of his experiments, and from them deduces the one important fact that the liver is modified by diet, and in particular that a mixed diet which contains a large amount of nitrogenous food throws a greater strain on the liver than a diet given in unrestricted amount, in which the nitrogenous elements are in smaller proportion. [J. B. H.]

THE EDINBURGH MEDICAL JOURNAL

OCTOBER, 1907.

6. MILES, A. *Résumé of Some Recent Papers on the Ultimate Results of Operations for Cancer of the Breast.*

2. Matthew presents his observations on the blood changes subsequent to excision of the spleen. His own case is of a laboring man of thirty-eight, who, while drinking one evening, was hit lightly in the splenic region by a friend. There were no signs until the following morning, when he began to suffer from severe pain in that region, with diarrhea, vomiting and all the signs and symptoms of an acute general peritonitis. On operation the spleen was found quite disintegrated and was removed. The blood was watched for over two years. He concludes that after the extirpation of the spleen there is (1) an enlargement of various lymphatic glands soon after the operation, but not to any great extent, nor of any great duration; (2) an absolute and relative increase in the number of lymphocytes persisting for years after the removal of the spleen; (3) a moderate eosinophilia with an increase of the blood plates for some weeks; (4) after recovery from the loss of blood, the red cells and hemoglobin show normal values; (5) after excision of the spleen individuals who recover suffer from no inconvenience; the spleen is consequently not indispensable.

3. Stuart presents a careful paper on operative injuries of the thoracic duct in the neck. He gives the details of his own case which was operated on for the recurrence of a cancer of the breast. He considers in detail the normal anatomy and the variations in anatomy of the thoracic duct, and discusses the various kinds of operative injuries. In the list of 40 cases of operative injury, which he has collected from the literature, 16 were for tuberculous glands, 20 for malignant disease. In 26 cases the injury was recognized during operation, in 13 cases it was not; 35 cases recovered, 5 died. As regards treatment, there were 15 cases in which ligature was used, 11 which were packed. He believes that ligature of the cut end of the duct is by far the best form of treatment in every case if possible. He concludes that operative injuries of this duct are probably far commoner than is generally imagined. He gives a careful summary of the 42 cases which he has been able to collect [J. B. H.]

12. Yonge gives a careful paper on the determining cause of the formation of nasal polypi. According to his observations the probable sequence of events is as follows: (1) chronic inflammation of the mucous membrane; (2) dilatation of the glands either through inflammatory closure of their orifices or hyper-filling of the glands due to over-stimulation; (3) edematous infiltration of the surrounding tissues, resulting from the passage of serum through the capillary walls, with (4) formation of folds or projections of the infiltrated mucous membrane; (5) increase of edema in certain of the folds, resulting in (6) the formation of flat edematous projections, the bases of which gradually become constricted or stretched until they form pediculated nasal polypi. He gives the pathological and clinical evidence on which this sequence of facts is based. [J. B. H.]

6. *WEDERHAKE. *To Ensure the Removal of all Compresses after Abdominal Operations.*
7. MÜLLER, G. J. *Status of Actinotherapy.* (Concluded.)

3. Heile calls attention to the diarrheas which are occasionally encountered in the after-treatment of operations on the gastro-intestinal tract. These he maintains are due to lack of alkali. The intestinal contents as it passes from the small into the large intestine always has an alkaline reaction in man and in dogs. The amount of alkali depends on the amount ingested and the amount of intestinal juice secreted. When the intestinal acids cease to be neutralized by alkaline elements, they have an irritat-

ing effect on the mucous membrane and diarrhea results. When the alkali ingested is not sufficient to keep the balance, and the intestinal juices are lost in the diarrhea, the organism suffers from alkali poverty, and in severe cases coma may ensue and acetone appear in the urine. In cases of inanition the urine should be examined for diacetic acid and acetone, and the history studied for previous diarrhea. After operations on the digestive tract ileus may develop and the patient succumb in coma from lack of alkali. Such patients should be fed with carbohydrates, and sodium bicarbonate should be given in various ways, even by intravenous injection of a 3% to 10% solution. Heile goes on to describe some cases in which vigorous treatment with alkalies apparently saved the patient. One case, after operation for suppurative peritonitis, was already in coma from post-operative ileus followed by profuse diarrhea. Opium treatment for the diarrhea, and administration of from 12 to 15 gm. of sodium citrate daily, arrested the diarrhea and prompt recovery followed.

4. Kaehler reports three cases of operation for typhoid perforation occurring in the Strasburg surgical clinic in the last two years. Two died and one recovered. All were in young individuals and during a relapse in the affection. He emphasizes the necessity of the earliest operation if any beneficial results are to be obtained.

6. Wederhake's method for avoiding the leaving of compresses in the abdomen after operation consists of using a square yard of gauze cut nearly into quarters, a small circle in the center of the square being left untouched. By this method the four quarters are left attached to each other in the center. If desired the squares can be cut into eighths, all united in the center, and the square can be of several thicknesses of gauze. He then uses these quarters or eighths as separate compresses, and finds them as convenient as if they were separate. When ready to suture the abdomen, the entire set of compresses is lifted out together, not requiring any counting.

[L. G. M.]

Münchener Medizinische Wochenschrift. No. 35. Aug. 27, 1907.

12. Herse, E. *The Action of the Quartz Lamp on the Deeper Tissues.*
13. Köhler, F. *Obituary on Theobald Kerner.*

3. Schüffner in making blood cultures from typhoid patients uses bile agar plates, on which the blood is poured. With this procedure he has excellent success. He finds two kinds of colonies, one the usual form of typhoid colony, small and discrete, the other much larger, and growing with great rapidity. This latter form of typhoid colony has never been observed before.

6. Walko has observed a series of chronic lead poisoning cases, 49 in all, with especial reference to the gastric condition. He finds disturbance of the gastric function, characterized by an absence or great diminution both of free HCl and gastric ferments, with a coincident lessening of motility. These disturbances are of long duration, and are usually functional, though occasionally organic changes in the gastric mucosa are met with. [R. D.]

Berliner Klinische Wochenschrift. No. 33. Aug. 19, 1907.

5. Lipschitz, R. *Remarks on Facial Paralysis.*
6. Clenna, W. N. *A New Iron Preparation.*

2. Kentzler, in a series of experiments, shows that the process of preparing albumin for absorption takes place in the stomach. Further experimentation has shown that it is the hydochloric acid of the stomach, in certain definite cencentrations, which brings about this transformation. Pepsin, the author claims, has no effect on the process.

3. Weil and Tsuda have found that in the case of the bacillus of dysentery, the presence of dysentery aggressin delays phagocytosis by guinea pig's leucocytes. This is a specific reaction, for no effect was produced on the phagocytic power for hay bacilli and staphylococci. This lessening of phagocytic power does not depend on removal of the opsonins, for it appears also when bacteria already under the influence of opsonins are exposed to the action of the aggressin. Loss of phagocytic power is, therefore, an active process, by which aggressin protects the bacterium from the phagocyte.

4. The author describes the symptomatology, and characteristic blood findings of Kala-azar, as seen in South Africa and Asia. The clinical picture is characterized by chronicty, marked splenic tumor, anemia, leucopenia and edema. The portal of entrance for the parasite, whose presence is characterized by the "Leishman-Donovan bodies," is undoubtedly through the gastro-intestinal tract. The host of this parasite the authors consider to be certain kinds of fishes. [R. D.]

No. 34. Aug. 26, 1907.

1. *Hölker. *Sporadic Cases of Epidemic Cerebrospinal Meningitis, and their Diagnosis.*
2. *Benjamin, E., and Sluka, E. *A Chronic Blood Disease, Accompanied by Long Standing Icterus (Chronic Acholuric Icterus).*
3. Proskauer, F. *The Employment of Guaiacol Preparations in Anemic Conditions.*

7. Glücksman, G. *Congestive Conditions of the Pelvic Organs in Relation to Appendicitis.*
8. Barth, E. *Functional Disorders of the Voice and Their Treatment.*
9. Laqueur, A. *New Views on Hydrotherapy.*

1. Hölker reports nine cases which clinically seemed to be sporadic cerebrospinal meningitis; in two of these the specific organism of Weichselbaum was not found until between two and five weeks after onset, though repeated attempts to obtain it were made. In six other cases, all of which closely resembled cerebrospinal meningitis, lumbar puncture or autopsy revealed other etiological factors. Two cases of purulent tuberculous meningitis were seen, in which polynuclear leucocytes predominated in the spinal fluid. The absence of lymphocytosis of the spinal fluid, therefore, does not positively exclude tuberculous meninigitis.

2. Benjamin and Sluka report the cases of a grandfather, father and child, without luetic history, who suffered from chronic icterus, the latter two from birth. All had urobilin, but no bile in the urine, with the normal amount of bile in the stools. Each one gave the same blood picture, that of a severe anemia. The father and child had marked enlargement of the spleen. The authors consider that either there was present an inherited anomaly of the hematopoetic system, or that these individuals were under the influence of some toxin, which affected the bloodmaking apparatus.

6. Mendel has shown that in certain organic nerve diseases, a tap on the dorsum of the foot produces plantar flexion of the toes, the great toe excepted, and that in

health there is a dorsal flexion. The author has tried this in 10 cases of organic nerve disease, in which no Babinski was present, and found Mendel's reaction positive in each case. [R. D.]

The Influence of Salt in the Diet on Arterial Tension. R. BAYER (*Arch. für Experimentelle Pathologie und Pharmakologie. Bd.* 57. *Hft.* 1 and 2, p. 162) reports from Krehl's clinic very interesting observations on the effect of changes in the salt content of the diet in cases of arteriosclerotic hypertension. A practically salt-free diet (about 4 gm. NaCl per diem) invariably reduced the blood pressure by considerable amounts, frequently as much as 30 mm. Hg, while the addition of 15 gm. of salt to this diet always gave a marked rise in the blood pressure, considerably above that noted on an ordinary hospital diet. All of these cases showed a well-marked salt retention, that is to say, the salt administered was only in small part excreted within twenty-four hours. It should be particularly noted that these were all cases of arteriosclerosis in which with increased tension there was no evidence of nephritis. This work is of great value, for it shows how the blood pressure may be reduced without the use of drugs, and explains the fact, already known, that a milk diet will reduce the tension, a milk diet being one containing relatively small amounts of salt. In nephritis, on the other hand, the same rules do not seem to apply. C. Loewenstein (same Journal, p. 137), working also at Krehl's clinic, was unable to obtain any constant results on blood pressure by varying the amounts of salt in the diet, contrary to the experience of several French observers. Out of 10 cases only one showed a marked increase of pressure after the administration of salt, and in one case of chronic nephritis, in which there was a very marked salt retention, the blood pressure actually decreased during the administration of large doses of salt. It is interesting to note that in two instances after large doses of salt, edema of the lungs occurred, but was relieved by the use of cardiac stimulants and venesection. The administration of large amounts of salt to nephritics is therefore no indifferent procedure, and requires careful watching of the patient. [W. T.]

Miscellany.

THE INTERNATIONAL CONGRESS ON TUBERCULOSIS.

PROGRESS along all lines connected with the International Congress on Tuberculosis, which is to take place in Washington from Sept. 21 to Oct. 12, 1908, was shown by the reports presented at a meeting of the Committee of Arrangements, held in New York, at the Associated Charities Building, Monday evening, Oct. 28. Dr. Lawrence F. Flick, of Philadelphia, chairman of the committee, presided, and the other members present were: Dr. Joseph Walsh, Philadelphia, secretary; Dr. John S. Fulton, Washington, secretary-general; Mr. William H. Baldwin, Washington; Dr. Hermann M. Biggs, New York; Dr. Frank Billings, Chicago; Mr. Edward T. Devine, New York; Mr. Livingston Farrand, New York; Dr. J. C. Greenway, Greenwich, Conn.; Dr. Chas. J. Hatfield, Philadelphia; Dr. Abraham Jacobi, New York; Dr. Alfred Meyer, Mrs. James E. Newcomb, New York; Gen. Geo. M. Sternberg, Washington, and Dr. Wm. H. Welch, Baltimore.

The meeting was the first held since Dr. Flick's return from abroad, and his reports of his visits to the International Conference on Tuberculosis in Vienna and to the International Congress on Hygiene and Demography, at Berlin, were interesting features of the session. More than a thousand delegates were registered at Vienna, he said, and the gathering at Berlin was quite as large. The leading men in both associations are looking forward with a great deal of enthusiasm, Dr. Flick said, to the meeting in Washington, next year, and about four hundred of the members of the foreign organizations may be expected to attend the Congress. The Conference selected this country as its place of meeting in 1908 just as the Congress did two years ago. The Conference and the Congress are two distinct organizations. The International Conference on Tuberculosis meets every year and keeps up a continuous organization with headquarters in Berlin. The International Congress on Tuberculosis meets only once in three years and does not maintain an international bureau in the intervals. Dr. Flick stated that at the International Conference, interest centered especially in the time-worn subject of the routes of invasion for the tubercle bacillus. It seems to have been demonstrated that the disease may be contracted by both the respiratory route, and the alimentary route. Though this does not make us much wiser in a practical way, still it is somewhat comforting to know that the respiratory route is less important than it was once thought to be. On the other hand, that information is compensated by the importance of the alimentary route.

In connection with his account of the progress made in the preliminary arrangements for the International Congress on Tuberculosis, Dr. John S. Fulton, the secretary-general, reported that ten distinguished foreigners have consented to participate in the series of special addresses that are to form a part of the program. The names of these eminent specialists follow: Dr. R. W. Philip, Edinburgh; Dr. C. Theodore Williams, London; Dr. Arthur Newsholme, health officer, Brighton, England; Dr. C. H. Spronck, Utrecht, Holland; Dr. Karl Turban, Davos-Platz, Switzerland; Dr. Gotthold Pannwitz, Charlottenburg; Dr. Emil von Behring, Marburg; Dr. A. Calmette, Pasteur Institute, Lisle, France; Dr. Maurice Letulle, Paris; and Dr. S. Kitasato, Tokyo, Japan.

Dr. Fulton also reported that up to the date of the meeting, the governors of twenty-three states had lent official auspices to the Congress. This not only insures official representation so far as that many states are concerned, but it insures an active organization in each of these states, that will be interested in the Congress. The states in which this action has been taken so far are: California, Utah, Montana, North Dakota, Minnesota, Wisconsin, Illinois, Iowa, Indiana, Michigan, Ohio, Kentucky, Kansas, Tennessee, South Carolina, North Carolina, Maryland, New York, Massachusetts, Vermont, Maine, West Virginia, Missouri.

Reporting on the formation of state committees, the secretary-general said that such committees had been appointed in nearly all of the states in the United States; that several have already

organized and are earnestly at work. He reported also that replies have been received from various foreign countries in reference to the appointment of committees, and the replies indicate that the countries addressed will be represented in nearly every instance by exhibits, as well as by delegates.

Correspondence.

LETTER FROM LONDON.

[From our Special Correspondent.]

THE NINTH FARADAY LECTURE. OSLER'S WORKING COLONY FOR CONSUMPTIVES. AN OPEN-AIR SCHOOL.

LONDON, Oct. 18, 1907.

Mr. Editor: I have just returned from the Royal Institution, where the ninth "Faraday lecture" has been delivered by Emil Fischer, and delivered, as was pointed out by Sir James Dewar in seconding the vote of thanks proposed by Sir Henry Roscoe, on the same spot, at the same table, in the same lecture theater amid circumstances almost precisely similar that Sir Humphry Davy exactly, a hundred years ago to the day, demonstrated to the Royal Society the elements potassium and sodium he had then isolated; the year 1807 was indeed the *annus mirabilis* of the Royal Institution, and the eve of the historic nineteenth of October was now doubly honored. It has been said that the greatest discovery Davy ever made was Faraday, and on this occasion both were commemorated.

These facts are in themselves of sufficient interest to warrant my mentioning them in my letter to you, but when I tell you that the subject of the address was the relation of synthetical chemistry to biology and its substance a record of great achievements of the highest moment to physiology, to pathology and to medicine, you will, I am sure, exonerate me for some enthusiasm.

Organic chemistry may be said to be the offspring of biology, the direct descendant of the science of medicine, and though she has developed a vigorous and entirely independent growth, she now returns to lend her most potent aid to the solution of problems we were otherwise unable to solve.

The problems of digestion have been solved to some extent, and we know something about the chemistry of the end products of metabolism, but we have always been in the dark about the changes that take place in the wonderful laboratory of the tissues.

The isolation of urea by Rouelle in 1773 and its synthesis by Wohler in 1828, forms the starting point not only of our conception of the identity of "organic" and "inorganic" chemistry, but also of the long series of syntheses of substances occurring in animal and vegetable tissues, culminating in the artificial production of polypeptides, which closely resemble peptones and proteins.

The construction of organic matter begins in the leaves of plants with the conversion of CO_2 into sugar. Fenton has converted CO_2 into formaldehyde; von Paeyer and Loew have produced from this, by heating it with lime water, a sugar-like product in which Fischer has found an acrose which can be transformed into glucose. There is at present no evidence as to the exact part taken by the optically-active constituent of the chlorophyll granules, but Siegfried has shown that the simple amino-acids are capable of combining with CO_2, and in all probability the proteins offer sufficient opportunity for its fixation. The combustion of carbohydrates in the body is brought about by means of oxidizing enzymes, but we know nothing of the composition of the enzymes because the complete isolation of an enzyme has never been accomplished.

The synthesis by Stolz of the crystalline adrenalin isolated by Takamine, indicates that it has a relatively simple structure; the same is true probably of "secretin," which has the property of liberating enzymes from the pancreas, and Fischer has demonstrated the exact dependence of enzyme action upon close similarity in stereo-configuration between the enzyme and the substance it attacks, a geometrical relationship so close that the lecturer applies the simile of lock and key for its expression.

Since the stereochemistry of the glucosides and polysaccharides is well understood, some idea of the configuration of the enzymes may be inferred, and their synthesis thus becomes not impossible within the near future.

To unravel the constitution of the proteins, hydrolysis by acids, alkalies and digestive ferments has been employed, and nineteen of the ultimate products, amino-acids, have been isolated, five of them in the twentieth century. Of these only three remain to be synthetized, and those already produced artificially have even been obtained in their optically-active form. Moreover, Professor Fischer has been able to refer the configuration of some of them to that of glucose.

Fischer and Abderhalden have prepared a peptide, l-leucyl-triglycyl-l-tyrosine which has all the properties of the albumoses, and the knowledge gained from the synthesis of this and many other peptides has opened up new ways of investigating the peptones and albumoses analytically. Chemists confidently expect to accomplish the artificial production of the nucleins, lecithin and cholesterin in the immediate future.

It is in fact due to the labors of organic chemists that we find ourselves within measurable distance of an understanding of the intimate nature of the bodily processes which it is essential we should possess for the proper appreciation of the morbid conditions that constitute disease and the means for rational therapy.

At the conclusion of the lecture Lord Rayleigh presented to Professor Fischer the Faraday medal of the Chemical Society.

Since my last letter we have had the annual meeting of the British Medical Association at Exeter, at which the privilege of listening to eloquent speeches by several physicians and surgeons from your side of the water was properly appreciated; the second International Congress of School Hygiene and the meeting of the British Association; but these are all so fully reported that you need no words from me on them.

If space permitted, I should like to tell you something of the scheme initiated at a little sanatorium down in Oxfordshire in which Osler has interested himself, for the establishment of a working colony for consumptives, where even the poorest can find opportunity to earn something by light employment as soon as they are able, and so prolong their stay away in the country under conditions as to air, food and hygienic discipline suited to the attainment of permanency in their cure, instead of returning to the unfavorable surroundings of work in the cities which so often results, if not in a fatal issue, at least in that "hope deferred" which "maketh the heart sick."

The London County Council has put into operation this year an "open-air school" on some high woodland to the southeast of London to which we have been very glad to send some of our little hospital patients, with, so far as my experience goes, the happiest results.

We could wish that the Imperial Parliament showed a tithe of the intelligent appreciation of the disinterestedness of the measures proposed by preventive medicine possessed by the London County Council.

C.

"PROSTATECTOMY IN TWO STAGES BY SPECIAL TECHNIC."

NEW YORK, Oct. 27, 1907.

Mr. Editor: In the issue of your valuable JOURNAL for Oct. 24, 1907, there is an article by me entitled "Prostatectomy in Two Stages by Special Technic."

Thinking that I should see proof of the article before it was published, I was not as careful in the construction of sentences and punctuation as I should otherwise have been. Unfortunately, owing to a change in my address, the proof did not reach me.

On page 556 of the JOURNAL, under the third division of conclusions, the sentence should read: "Its advantages are: the quick relief afforded, slight shock and absence of serious symptoms."

Very truly yours,

FOLLEN CABOT, JR., M.D.

RECORD OF MORTALITY

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING NOVEMBER 2, 1907.

H. A. MAY, passed assistant surgeon. Commissioned passed assistant surgeon from April 22, 1907.

R. E. LEDBETTER, passed assistant surgeon. Ordered to the Navy Yard, Norfolk, Va., Nov. 14.

A. STUART, passed assistant surgeon. Ordered to the "Yankton" Nov. 5.

M. BOLAND, assistant surgeon. Detached from duty at the Naval Hospital, Norfolk, Va., and ordered to course of instruction at the Naval Medical School, Washington, D. C.

W. N. MCDONOLL, assistant surgeon. Detached from the "Yankton" Nov. 5, and ordered to the Naval Hospital, New York, N. Y.

G. T. GRAYSON, passed assistant surgeon. Detached from the Navy Yard, Washington, D. C., and ordered to the Naval Dispensary, Washington, D. C.

F. E. PORTER, assistant surgeon. Detached from the "Franklin" and ordered to the Navy Yard, Washington, D. C.

G. W. SHEPARD, assistant surgeon. Appointed assistant surgeon from Oct. 25, 1907.

R. A. CAMPBELL, acting assistant surgeon. Ordered to the "Franklin."

J. C. THOMPSON, surgeon. Detached from the Naval Station, Olongapo, P. I., and ordered to the "Chattanooga."

R. T. ORVIS, surgeon. Detached from the "Chattanooga" and ordered home.

I. F. COHN, assistant surgeon. Detached from the "Elcano" and ordered to the Naval Station, Olongapo, P. I.

SOCIETY NOTICES.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY IN CONJUNCTION WITH THE BOSTON MEDICAL LIBRARY MEETING. — Wednesday, Nov. 13, 1907, at 8.15 P.M., John Ware Hall. The Treatment of Inoperable Sarcoma with the Mixed Toxins of Erysipelas and Bacillus Prodigiosus; Dr. William B. Coley, New York. 1. Method of Preparation with Recent Modifications; 2. Technique of Administration; 3. Indications for Use; 4. Prognosis, as determined by Analysis of Final Results. Trypsin in the Treatment of Cancer, Dr. Wm. P. Graves. Discussion by Dr. R. C. Larrabee. Light refreshments after the meeting.

J. C. MUNRO, *Chairman.* J. C. HUBBARD, *Secretary.*

NEW YORK ACADEMY OF MEDICINE. — The anniversary meeting and reception will be held Friday evening, Nov. 29, at 8.30 o'clock. The anniversary discourse will be delivered by Col. W. C. Gorgas, M.D., U. S. A., chief sanitary officer, Isthmian Canal Commission. Subject, "Sanitation of the Canal Zone." Stereopticon illustrations. Fellows desiring extra invitations will please notify the committee on anniversary meeting.

ERRATUM.

The word suggested by Dr. Edward A. Ayers, in his recent Carpenter Lecture, to best name in one word, instead of a phrase, an important class of diseases, was "homomosquitic," and not "homosquitic" as given in our report.

RECENT DEATHS.

CHARLES WILLIAM BURTON, M.D., M.M.S.S., died in Adams, Oct. 5, 1907.

CHARLES BRET POOL, M.D., M.M.S.S., died recently in Lowell, aged thirty-eight years.

HENRY RUPERT BRISSETT, M.D., M.M.S.S., died in Lowell, Oct. 18, 1907.

DR. FRANK HENEL, of New York, died on Oct. 28. He was graduated from the medical department of the University of the City of New York in 1875, and was for some time in the service of the Health Department. For many years he was associated with the municipal institutions on the East River islands, and at the time of his death was consulting physician to the City Hospital and the Randall's Island Hospital.

DR. SETH D. CLOSE, of New York, committed suicide by taking strychnine on Oct. 29. He had been suffering for some time from melancholia, and had only recently returned, in apparently improved condition, from the Rivercrest Sanitarium at Astoria, where he had been under treatment for several weeks. Dr. Close, who was a well-known and highly respected practitioner in the Borough of the Bronx, was fifty-six years of age at the time of his death. He was born in Geneva, N. Y., and was graduated from the College of Physicians and Surgeons, New York, in 1876. He had lived for more than thirty years in the house where he died, and had seen the neighborhood which, at the time he took up his residence there, was a portion of Westchester County, change from a distinctly rural one to a thickly populated city suburb.

DR. V. PLOWDEN MCLAUGHLIN, of New York, died suddenly on Nov. 2 at Saranac Lake, in the Adirondack Mountains.

MUSCLE AND TENDON TRANSFERENCE.

BY E. H. BRADFORD, M.D., AND ROBERT SOUTTER, M.D., BOSTON.

THE following paper is based upon an analysis of 35 cases, with periosteal insertion and silk strand elongation, including one case of silk suture elongation of the hamstring to the os calcis, and two cases of pectoral trapezius anastomosis.

This procedure in surgery has already won its position in the list of surgical methods, but as there is still much discussion in regard to the question of technic, the careful recording of cases is at present desirable. The following cases are presented as indicating the results which can be obtained by the exercise of ordinary care.

The writers record their appreciation of the great value of the method of extending tendons by the use of silk strands. They wish to emphasize the necessity of the following points: First, the avoidance of disturbance of tissues as far as possible; second, the necessity of thorough asepsis, not simply such as is ordinarily necessary in surgical procedures, but in the preparation of the skin.

Silk strands have been, as a rule, used after having been boiled twice; in some instances the second boiling has been in a corrosive sublimate solution, in others, the simple boiling has been employed. They have not found that any particular advantage has followed, as far as they can determine, the boiling in sublimate claimed by Lange to be essential. As the number of cases is not large, definite claims cannot be made, but it is clear that the danger is not as great from silk not boiled in sublimate as has been suggested.

The dipping of the sterilized silk in solutions of celluloid has been used in one instance, and the method is open only to the objection of increasing detail.

The patient's skin has in two instances been protected with the ordinary means of sterilization by painting with iodine, and afterwards by painting with a solution of rubber in ether over the field of incision. This latter was applied to one limb, and where the other limb was also operated on the ordinary means of sterilization were all that were used. No perceptible difference was noted in this instance, and in the other cases the method was not used in order to avoid multiplication of details.

It is seen that in some of these cases a healing by first intention is not obtained. It can, however, be claimed that such a rule is regarded as desirable in all instances, and can be attained by the most careful attention to detail. It is for that reason, probably, that it is desirable, even at the expense of the multiplication of details, to carry out most thoroughly means for skin sterilization and for other sterilization.

It is desirable that the patients should be kept in a plaster fixation for as short a time as possible, plaster only being applied for a sufficient length of time to secure a healing of the skin incision, and a reasonably strong tissue healing.

After this the apparatus treatment should be begun, with apparatus devised in such a way as to prevent any strain upon the transferred tendon. Massage, muscle training and graded exercises are essential in the after-treatment for several months.

It cannot be claimed that a complete restoration to normal strength can be accomplished in tendon transference. In many instances little can be accomplished, as it is impossible to transfer muscles effectively, if there are no strong muscles to be utilized; but in the larger number of cases considerable benefit can be obtained, and in a certain number surprisingly good results can be secured.

The method of tendon arthrodesis, as described by the writer in an article presented to the society two years ago, has been performed three times. The ultimate result after three years in one case was extremely satisfactory; a sloughing out of one strand delayed the cure in the second case, and in the third case the final result cannot be determined, as the operation has only been recently performed but in both cases excellent results are promised.

An analysis of cases of tendon transference chiefly without silk strand elongation, treated at the Boston Children's Hospital for the previous ten years, was reported two years ago.

The following cases are additional ones, operated upon by the writers, both at the Children's Hospital and elsewhere, with the transference of tendons lengthened by silk strands.

TENDON TRANSFERENCE WITH SILK ELONGATION FOR DEFORMITIES OF THE FOOT.

CASE I. J. B., age, ten years. Operation, Sept. 7, 1905. Infantile paralysis, requiring transference of the tibialis posticus and a portion of the flexor communis digitorum into the scaphoid and cuboid for paralytic equino-varus. The result early in the year 1906 was good, with power of dorsal flexion and good adduction. The patient walks without apparatus.

CASE II. M. M., age eight and a half years. Operation August, 1905. Paralytic calcaneus. Wedge section of the os calcis, with the transference of the tibialis posticus with an insertion on the calcaneus. Silk elongation. Results, Nov. 14, 1905, good position.

CASE III. E. L. R., age eight years. Operation, September, 1906. Infantile paralysis with foot drop, requiring transfer of two slips of common extensor of toes to cuboid, and two other slips to the inner side of the foot inserted into scaphoid. Result, better position, without gain in motion.

CASE IV. M. O., age seven years. Operation September, 1905. Peroneus longus and one half of the tendo Achillis into anterior part of astragalus by means of silk.

Result, in good position of foot. Has not reported recently to ascertain motion.

CASE V. M. W., age ten years. Operation August, 1906. Paralytic varus requiring the transfer of two slips of extensor of toes by silk into periosteum of cuboid, and removal of a wedge from the outer part of os calcis.

May, 1907, the foot is held in good position and has gained in motion and function. (Fig. 1.)

CASE VI. J. K. B., age five years. Operation Aug. 8, 1905. Half of the tendo Achillis was split and

brought forward and inward by silk elongation into the scaphoid. The result, when last examined, was good as to position and use.

CASE VII. F. B., age eight years. Operation Aug. 11, 1905. For paralytic equino-varus. Half the tendo Achillis was brought forward to the scaphoid and cuboid by tendon transference with silk elongation, shortening of the tibialis anticus and peroneus longus. Result, good position and functional use.

CASE VIII. R. C., age nine years. A similar condition justifying a similar operation Aug. 16, 1905, with an excellent immediate result. March 19, 1907.

CASE IX. A. F., age ten years. Operation August, 1905. Equinus; insertion of half of the tendo Achillis elongated by silk strands into the scaphoid. Good result in motion and position. March, 1907.

M. W. CASE V. FIG. 1.

Transference of flexor communis digitorum, with silk strand insertion on inner and outer sides of dorsum of the foot to correct front foot drop.

Other view of Fig. 1, showing the regained power of raising front of foot.

CASE X. E. R., age nine years. Operation Aug. 22, 1905. Insertion of a portion of the flexor communis digitorum and a portion of the tendo Achillis into the scaphoid and cuboid by silk elongation; stretching of the hamstrings. Result, good position, and more motion. March, 1907.

CASE XI. W. M. K., age eight years. Operation Aug. 22, 1905. For equino-valgus. Transference of a portion of the flexor communis digitorum and of the tendo Achillis to the scaphoid by silk elongation, with tenotomy of the tendo Achillis. More motion and better position "when he tries." March, 1907.

CASE XII. A. C., age eight years. Operation Aug. 24, 1905. Paralytic equino-varus. Osteotomy of the scaphoid and os calcis, foot twisted and tenotomy of the tendo Achillis. More motion, good position and use of foot. March, 1907.

CASE XIII. G. D., age six years. Operation Aug. 28, 1905. Paralytic equino-varus. Transference of two slips of the flexor communis into the cuboid, tenotomy of the tendo Achillis. Result, good position and use of the foot; a little more motion and better position. March, 1907.

CASE XIV. M. B., age seven years. Operation Sept. 7, 1905. Paralytic valgus. Transference of the peroneus longus and half of the tendo Achillis into the anterior part of the astragalus. Tenotomy of the tendo Achillis. Silk elongation. Immediate result satisfactory. Final result not known.

CASE XV. J. K. A., age seven years. Operation Sept. 26, 1905. Paralytic varus. Transference of outer half of the tendo Achillis into the cuboid with silk elongation. Operative result satisfactory. Ultimate result not known.

CASE XVI. H. A. R., age eighteen years. Operation, August, 1906. Infantile paralysis when ten years of age; worn apparatus for some time. Foot drop. The flexor longus transferred and silk strands inserted into the dorsum of the foot; shortening of the common extensor of the toe; tenotomy of the tendo Achillis. The wound healed, except a superficial granulation in some portions of the incision. The result three months after the operation was good, position of the foot and slight muscular power of flexion. Result, nine months later, good position and function and gain of movement in all directions in the foot. The foot drop.

CASE XVII. E. R., age five years. Operation June, 1906. Transference of a portion of the flexor communis digitorum by lengthened silk strands into the dorsum of the foot with two insertions, one on the inner and the other on the outer side. The immediate result was healing by first intention with good position. Ultimate result not yet determined.

CASE XVIII. R. W., age sixteen years. Operation August, 1906. Slip of flexor longus digitorum inserted by lengthened silk strands, both externally and internally, into the dorsum of the foot. Healing by granulation. Ultimate result six months later reported to be good.

CASE XIX. E. S., age three years. Operation April, 1907. Tendon transplantation of common flexor, lengthened by silk strands and inserted on the outer and inner side of the foot. Healing by first intention. Ultimate result not yet determined.

CASE XX. F. W., age ten. Operation September, 1906. Infantile paralysis requiring transfer of outer portion of common extensor of toes into cuboid by means of silk. Tenotomy of plantar fascia and tendo Achillis. A wedge was removed from the outer part of the astragalus. Good position of foot for use and function. March, 1907.

CASE XXI. E. W., age seven. Operation April, 1906. Infantile paralysis, requiring tenotomes and transfer of peroneus longus by means of silk strand to periosteum of scaphoid and shortening of paralyzed tibialis anticus and of extensor of toes. Result, March, 1907, better position of foot, some motion at point of transfer.

TENDINOUS FIXATION OF THE ANKLE JOINT FOR FRONT FOOT DROP.

Two cases of this procedure were reported in a previous paper. The operation being indicated where the paralysis is so extensive that no muscles offer sufficient strength for transference, the following three cases are mentioned, although recently performed, as suggesting some operative details. In the previous operations the silk strands were passed through a hole drilled in the tibia, and the tendons of the extensor communis were inserted and attached in a chiselled groove in the tibia. In one of these operations some sloughing followed and there was a delay in healing. A good ultimate result finally followed. In

the other cases prompt healing occurred without sloughing of the silk, and there was marked improvement in gait and entire correction of the toe drop. In the four following cases no bone attachment was attempted, the attachments being periosteal.

Case XXII. C. F., age fifteen years. Operation June, 1906. Portions of the tibialis anticus and peronei tendons freed from muscular bellies and sutured to the periosteum of the tibia. Silk strands inserted sub-periosteally in the inner and outer side of the dorsum of the foot. The strands were then passed upwards subcutaneously to the incision on the upper portion of the leg, passing under the annular ligament, and secured into the periosteum surrounding the tibia. The tendo Achillis was divided. The wounds healed by first intention. Ultimate result, nine months later, improved position of the foot. Almost complete correction of front foot drop. Walks without apparatus. March, 1907.

Case XXIII. M. S., age seven years. Operation February, 1907. Silk quilted through the periosteum about the tibia, three inches above the malleoli, passed subcutaneously under the annular ligament, and posterior insertion on the outer and inner side of the dorsum. Anterior tibial and common extensors attached three inches above the joint to the periosteum of the tibia. The wound healed by first intention. Ultimate result, foot held with entire absence of toe drop and with marked improvement in gait. May, 1907.

Case XXIV. R. P., age eight years. Operation April, 1907. Complete paralysis of the extensor communis, peronei and tibialis anticus. The silk strands were quilted in the upper end into the periosteum of the tibia three inches above the ankle joint. The silk strands were then passed under the annular ligament and inserted on to the dorsum on the outer and inner side of the foot. A split portion of the tendo Achillis was removed and transferred, with silk elongation inserted into the outer and inner side of the dorsum of the foot. Strands from the tibialis posticus and tibialis anticus were dissected off three inches above the ankle joint and stitched by quilting stitch into the periosteum around the tibia. The tendo Achillis was divided. Immediate result, healing by first intention, with good foot fixation.

Case XXV. M. S., age seven. Operation February, 1907. Silk strands passed through tibia and made fast to cuboid on one side and to scaphoid on the other, holding the foot at right angles. Result, foot held at right angles.

As the operation in the last two cases is recent, the ultimate result is at present undetermined, but there seems no reason to think that the usefulness of the limb will be less good than in the other cases previously reported.

TENDON TRANSFERENCE FROM THE HAMSTRINGS TO THE OS CALCIS BY ELONGATED SILK STRANDS.

Case XXVI. E. D., age eight years. The following unusual operation, performed by Dr. Soutter, August, 1905, is of clinical interest, particularly from the fact that the procedure is an unusual one. The soleus, extensors and plantaris were paralyzed, the foot being held in the position of calcaneus. There was no flexor function of the toes, but there was good power in the hamstrings. A silk strand was quilted into the semimembranosus and extended downward and fastened to the os calcis.

The case was lost sight of for over a year, and when examined, the attachment of the silk in the os calcis was firm. The patient walked without the calcaneous deformity, there was tendency to valgus and abduction of the front of the foot existed; but after four weeks of muscle training, the foot could be extended in the plantar flexion direction without flexion of the knee. The foot is held, at present, a year and a half later, in a good position, and some flexion in the toes is possible. May, 1907. Plantar flexion of the foot, due to the transfer, is strong enough for use.

FOOT AND KNEE.

Case XXVII. H. M., (1) age eight years. Operation April, 1907. Transference of portions of the flexor communis, lengthened with silk strands inserted into the outside and inside of the dorsum of the foot. External hamstrings lengthened with silk inserted subperiosteally on either side of the patella, and continued and inserted into the tubercle of the tibia.

This operation was performed on the left leg. In the right foot, transference of portions of the flexor communis, with extension of silk strands and insertion on the outer and inner side of the dorsum of the foot. Healing by first intention throughout. Immediate result, good position and slight gain of motion. Ultimate result not yet determined.

Case XXVIII. W. D., age twelve years. Operation January, 1907. Paralysis of the quadriceps extensor, tibialis anticus and peronei. Transference of outer hamstrings, with silk elongation to the patella and tibial tubercle. Transference of the flexor longus with silk strands inserted into the dorsum of the foot. Healing in part by first intention, and in part by skin granulation. The present result is good position, with slight muscular power in all directions. Under gymnastic exercises this is increasing.

Case XXIX. M. H., age eight years. Operation August, 1906. Tendon transference of the flexor longus digitorum with silk insertion in the anterior portion of the foot; transference of the gracilis and a dissected portion of the iliotibial band serving as tendon of the tensor vaginæ femoris into the patella by silk strands, and into the tubercle of the tibia. Healing by first intention, except the incision on the inner side of the hamstrings, which healed by granulation. Condition, April, 1907, excellent, with power of motion in extending the leg, and complete cure of toe drop, with slight motion in foot extension, abduction and adduction.

Case XXX. R. R., age seven years. Operation July, 1906. Tenotomy of both tendines Achillis. Transference of a portion of the iliotibial band; gracilis and semimembranosus inserted into the patella. More motion, good position. April, 1907.

Case XXXI. J., age twenty years. Operation Feb. 22, 1906. Paralysis left leg, extensor communis, and dorsal extensors of the foot. Outer hamstring was transferred forward with silk elongation, and inserted into the patella on both sides and on the ligamentum patellæ. Transference of flexor communis with tenotomy of the tendo Achillis. Wounds healed by first intention, except two incisions, which healed by granulation. At present, April, 1907, absence of foot drop, and slight power in motions in all directions of the foot and at the knee.

Case XXXII. S. M., age nine and one half. Operation Sept. 19, 1906. Semimembranosus transferred with silk strands to patella, and flexor longus digitorum put into cuboid. Tendo Achillis lengthened by tenotomy. Patient had complete paralysis of the other leg, and for four years previous to operation he crawled on his abdomen, using his hands for locomotion. March, 1907, his uncle reported that he was walking on the operated leg and crutches.

CASE XXXIII. H. W., age seven. Operation September, 1906. Infantile paralysis, requiring transfer of semimembranosus into the patella, by means of silk strands. Tendo Achillis split and one half carried forward to outer side to cuboid. Immediate result good. Ultimate result not known as yet.

SHOULDER.

The writers have already reported two cases of transference of a portion of the trapezius to the insertion of the deltoid for deltoid paralysis. They are able to add three cases of shoulder paralysis. In two the pectoralis major was cut down upon and a portion of the muscle freed and the same thing done with the trapezius; the separated muscular bands were united firmly. Giving an insertion of the elongated trapezius into the humerus.

CASE XXXIV. E. W., age five years. Operation July, 1906. Paralysis of the deltoid and triceps, with some power of the outer part of the biceps. The pectoralis muscles strong as was also the trapezius. Transference of portion of the trapezius forward with silk strands elongation into a portion of the tendon of the pectoralis major, which was freed from its muscular attachment, making for it an insertion into the humerus. The wound healed by first intention, and the ultimate result to date is restoration of the power of elevating the arm 45° above the height of the shoulder, with some anterior motion.

CASE XXXV. B., age eight years. Operation September, 1906. Paralysis of the right deltoid, but with some strength in the biceps. Transference of the trapezius with silk elongation insertion into the periosteum at the place of the deltoid insertion. Result, February, 1907, patient has improved power, can elevate the arm above the shoulder.

CASE XXXVI. D. R., age five years. Operation 1905. Paralysis of the deltoid, triceps and of biceps. Congenital dislocation of the shoulder subcoracoid. A portion of the trapezius separated from its insertion, one half of the pectoralis major tendon and some muscle fibers cut and separated from the rest of the muscle. This insertion of the pectoralis sutured to the freed fibers of the trapezius, forming an insertion for it in the humerus. One year later good use of arm in anterior motion and without tendency of shoulder to drop subcoracoid.

The after-treatment in these cases consisted of fixation of the arm by plaster of Paris bandages in a position extended above the head, so as to raise as far as possible the inserted portion of the muscle. Plaster of Paris fixation was continued for six weeks. The arm was then placed in a less elevated position by a second plaster bandage, which was worn for a month. Later a right-angle wire arm support, keeping the arm and hand at right angles with the trunk, was worn, accompanied by beginning use, gymnastics, etc.

The result in these cases up to date corresponds with the result in two previous cases reported in the previous paper two years ago, the result of which has continued to be as satisfactory as when reported.

The details of the operative procedure in all these cases varied but slightly. They were all performed upon cases with slight or no resistant deformity, beyond tendon shortening, and without great structural changes of tendon and muscular tissue. In all cases complete correction by force or tenotomy or both of the existing deformity was made before the muscle transference, with overcorrection in the resistant cases. The silk strands were inserted by quilting in the divided tendon, which was cut off as low down as possible. As small skin incisions were made as were feasible, but enough to expose adequately the muscle and tendon, and to enable the tendon to be transferred with as little of an angle of the transferred tendon as possible.

The transferred tendon or strand was covered by fascia specially sewed over it independent of the sewing of the skin incision. As a rule, no drain was placed in the wound, which was sewed up by catgut. The limb was placed in a moderately corrected position in a plaster bandage. As a rule, the wound was not examined for ten days or a fortnight. In most of the cases reported, the wound healed by first intention, either entirely or partially. In portions of the wounds there was superficial gaping. In none of the cases was there any evidence of sepsis, and no sloughing out of the tendons, although in the first cases operated upon by silk transference five years ago, sloughing of the silk occurred in five instances.

The periosteal insertion on the dorsum of the foot was made with care, a curved handled needle being used, taking a firm grip upon the periosteum. Bone drillings were not used.

The usual after-treatment in these cases was plaster fixation for two months, followed by apparatus which would prevent toe drop or abnormal strain, followed, when practicable, by muscle training, massage and gymnastics for several months.

It is difficult to determine in all cases when plaster bandage fixation should be omitted, and some functional activity of the muscle allowed. The matter is one of judgment and no fixed rule can be stated, as much depends upon the weight of the limb and the age of the patient. It may be considered as a general proposition that as soon as firm healing has been established, slight functional activity of the transferred muscles should be allowed in order to favor the formation of strong tissue.

In order to obtain the best ultimate result, the cases should be followed carefully, with a well-regulated treatment directed to the development of the weakened muscles; in many instances much gain can be effected in muscles previously considered beyond repair.

In cases of this class it is difficult to record and report the exact degree of improvement, as a slight amount of gain in a muscle apparently incapable of exerting functional power justifies in a child an expectation of greater gain under persistent care.

In the cases here reported all apparatus was removed at the end of either six or nine months following the operation, and in many cases increasing improvement followed the release from apparatus, with a gain of power from use.

The conclusions which the writers have drawn from their cases of tendon transference is in accord with the experience of many other surgeons, viz.:

That tendon transference is a procedure which offers with a minimum of risk a chance of great benefit. In none of the cases reported were the patients not benefited by operation, either by an improved position, or gain in functions. The immediate result in all was favorable, and the ultimate result in a number of cases surprisingly good.

A comparative study of the writers' cases previously treated by simple tendon transference without periosteal insertion and of tendon shortening of the relaxed tendons with the results gained by the careful employment of silk strand elongation of efficient muscles and periosteal insertion into selected and mechanically favorable points on the foot and tibia, demonstrates the superiority of the newer over the older method.

The strictest aseptic and antiseptic precautions are demanded. All of the operations herein mentioned were performed not only with all aseptic details as to the patient, instruments and dressings, but with the use of gloves and masks by the surgeon, his assistants and the assisting nurses.

The amount of benefit finally gained in function and correction of disability is in favorable cases so great as to justify an expectation of equal benefit in all cases. Even in extensive paralysis something can often be done to improve the condition.

THE SEASHORE TREATMENT OF THE TUBERCULAR ARTHRITIS OF CHILDREN.

BY ALBERT H. MILLER, M.D., PROVIDENCE, R. I.

Tubercular arthritis is esentially a disease of childhood, 85% of the patients who have applied at the Rhode Island Hospital for treatment for this condition having been under fifteen years of age. The course of the disease is chronic, its duration, for years, attended with the formation of abscesses and discharging sinuses and usually terminating fatally from tubercular meningitis, tubercular peritonitis, or some other intercurrent disease as the immediate cause of death.

The treatment of these cases has consisted of immobilization of the affected joints by braces or plaster casts and of various surgical operations for the removal of pus and diseased bone, or for the correction of deformities. Although this treatment has been efficient in diminishing the deformities of those patients who have survived, it has had little effect in lessening the suffering and fatality of the disease.

It is urged, with some appearance of reason, that an attempt to save the lives of patients with tubercular joint disease is opposed to the law of the survival of the fittest, and that these children should be allowed to die rather than to grow up deformed, to pass on their tubercular taint to succeeding generations. Opposed to this argument, is the fact that these crippled children suffer tremendously, not only the acute pain of burrowing abscesses and of muscular spasm, but also the constant discomfort from restraint of motion. Whatever our ideas may be as to the value of their lives, we must unite in believing that any time spent in freeing their distorted little bodies from suffering is time well spent.

Following the lead of the Children's Island Sanitarium at Marblehead and the Sea Breeze Sanitarium at Coney Island, the Rhode Island Hospital, in the summer of 1906, first opened the ward for the seashore treatment of the tubercular arthritis of children. The entire expense of the work was defrayed by the late James A. Garland, whose death cast a shadow over the last weeks of the summer's work. The Garland ward was located thirty-five miles from the city of Providence on Conanicut Island, in Narragansett Bay, where an old hotel, with good bathing facilities, was converted into a temporary hospital. This institution was open from the middle of July to the first of October.

There were 32 patients, 11 of whom came from the wards of the hospital in Providence. A great deal of care was taken in the selection of the patients. They were children under sixteen years of age, who were afflicted with tubercular arthritis and belonged to the following classes:

First, cases of extreme severity.

Second, patients living amid improper surroundings with insufficient nourishment.

Third, cases steadily failing from any cause. There were 20 boys and 12 girls. The average age was nine and one quarter years. The youngest was fourteen months old. In 14 cases, the hip was affected; in 9, the spine; in 7, the ankle; in 1, the knee and in 1, the shoulder. The duration of the disease had been from six months to eleven years. The average duration had been three and one-half years. Every patient had at some time been in the hospital for a period varying from one to thirty months. Twelve children had a total of 25 suppurating sinuses.

Realizing the influence of bad surroundings and improper food in the development of the disease, the treatment was largely hygienic, drugs being used only in an occasional emergency and no operating being done at the summer branch. Fresh air day and night, sea bathing, an abundance of nutritious food and freedom from restraint, both mental and physical, formed the basis of the treatment.

Seashore treatment of tubercular arthritis. The simple extension straps employed.

From sunrise to sunset, the children lived out of doors and the windows of their sleeping rooms were never closed. All the patients bathed in the salt water, as many as possible bathing every

day. The bath, which usually began at two in the afternoon, lasted for half an hour. The bathing was the feature of the day's pleasures.

Patients wearing hip braces bathed twice a week. Extension was made by two strips of ZO adhesive plaster two inches wide, one on the outside extending from the great trochanter to the knee and the other from an inch below the perineum to the inside of the knee, each terminating in a strip of one inch webbing which reached to the foot-piece of the brace. This arrangement of the extension, which could be removed and replaced every third day without irritating the skin, was free from the objection of pulling on the knee. On the bathing day, the brace and extension straps were removed and the patient bathed in the sea water. Every precaution was taken against movement of the affected joint while the brace was off, and as soon as the bath was over the patient was dried and the brace and extension were replaced.

Patients with plaster jackets were allowed to wade every day. Patients in bed were bathed every day on a frame or in a basket which was wheeled into the water.

Surgical dressings were done after the bathing hour. No chemical antiseptics were applied to the wounds. Drainage tubes and gauze packing of sinuses were not allowed. The soiled dressing was removed, the surface dried, and a sterile pad applied, which remained until after the next bath. On the days when the patients did not bathe in the ocean, the wound was cleansed with salt solution and a fresh pad was applied.

The diet comprised cereals, bread, crackers, meat, fish, vegetables, fruit, simple desserts, several eggs a day and two quarts of milk for each patient. Meals were served five times a day: at seven and ten o'clock in the morning, at noon and at three and five o'clock in the afternoon. Except breakfast on the piazza, meals were served picnic fashion on the lawn, on the beach, or wherever the children happened to be at the time. The patients developed astonishing appetites.

Every thing possible was done to make the patients happy and contented. Only a few rules were made; but these were rigidly enforced. The affected joints must at all times be kept quiet. With this exception, activity was everywhere encouraged. The patients played games, held baseball matches, wrestled, swam in the ocean, and had as good a time generally as any group of well children could enjoy.

This treatment was so radical a change from accepted orthepedic ideas that, day by day, the effects were carefully watched. The results were so good as to leave no room to question the wisdom of the methods used.

Eleven patients had come from the wards of the hospital; 12 had come in beds or wheel chairs;

Seashore treatment of tubercular arthritis. The patients shown above comprise ten tubercular hips, six spines, five ankles and one tubercular knee.

13 on crutches; and 7 walking unaided. At the end of two and one-half months' treatment, it was necessary to return only 2 to the hospital wards; 2 were in beds or wheel chairs; 18 on crutches; and 12 walking unaided.

An increased mobility with loss of sensitiveness was noted in the affected joints. The gain in weight averaged 2½ lb. per month. The greatest gain was 7 lb. in one week.

Of the 25 discharging sinuses, 11 were entirely healed. All sinuses were improved and several healed soon after the return from the summer hospital. Eight bed sores on one patient were entirely healed.

It was interesting to watch the condition of the patients during the winter following their first outing. They uniformly continued to improve for a time after returning to their homes. No one of the sinues which had healed broke out again. In most cases the improvement continued, but two patients began to fail after a few months and in the spring of 1907 were in practically the same condition as a year before. The cause of this failure was directly traceable to the surroundings and insufficient nourishment to which they were subjected.

With a plan of treatment so different from the accepted orthopedic practice, the results obtained are so far superior to those to which we have been accustomed that even our limited experience seems to have demonstrated as true the following principles:

1. Fresh air and an abundance of food, combined with sea bathing and freedom from unnecessary restraint, bring about a continuous, uniform and rapid improvement in all cases of tubercular arthritis of children.

(*a*) Orthopedic restraint should be applied only to the joint affected. Otherwise, activity should be encouraged.

(*b*) The beneficial effect of sea bathing more than compensates for any theoretical injury done by leaving off orthopedic apparatus for a short time daily.

2. Tubercular sinuses which are bathed in sea water daily and which have no other treatment save a protective dressing improve with surprising rapidity.

In most of the cases of tubercular arthritis, the patients are so improved by the summer treatment that they can safely return to their homes for the winter. A few cases require treatment during the whole year.

In preparing this paper, I have drawn freely from the report of the committee, consisting of Dr. Halsey DeWolf, Dr. J. M. Peters, and the present writer, who had charge of the Garland ward in the summer of 1906. The work is now being continued for the second year at the Crawford Allen Memorial, a branch of the Rhode Island Hospital, situated eighteen miles from Providence, on the west shore of Narragansett Bay.

An oil portrait of Dr. John Guiteras has been hung in the eastern amphitheater of the medical laboratories of University of Pennsylvania.—*Jour. Am. Med. Asso.*

Clinical Department.

TWO CASES OF HEMORRHAGE FOLLOWING THE REMOVAL OF THE TONSILS.

BY E. A. CROCKETT, M.D., BOSTON.

For about eight years I have been using, for the removal of nonadherent large tonsils, a Farlow tonsil snare, threaded with No. 5 steel piano wire, and in adherent tonsils it has been my practice to dissect off the tonsil with a Leland tonsil knife and then apply the snare as in the nonadherent type, removing such fragments of the tonsil as might remain with the tonsil punch. Prior to this method, I have been using either the tonsillotome or a long throat knife or scissors, and under this method of operation have had a number of severe hemorrhages, which several times succeeded in alarming me, but which always checked under pressure for a few moments without exsanguinating the patient.

Until last spring I had never seen a hemorrhage of even ordinary severity follow the use of the snare, and in addition have seen the tonsil more completely removed than by any other method of operating which I have ever employed, and have been accustomed to say that a severe hemorrhage was impossible to be obtained by this method.

About a year ago, I began threading my snare with a steel wire two sizes larger than the No. 5 formerly used. This wire makes a loop much easier to apply to the tonsil, but it does not apply itself so flexibly to the tonsil to the exclusion of other tissues as does the No. 5. I noticed, as soon as I began to use it, that the snare bit deeper into the tonsil fossa than I had been accustomed to see, but still I had no trouble until the first of the two cases reported to-night. It seems to me possible, although I am not convinced of it in my own mind, that this hemorrhage may have been caused by the use of this nonflexible wire. At any rate, I shall use in the future the No. 5, until I see some reason to change my opinion.

Case I. The first was a boy about eight years old, who had two large nonadherent tonsils and a large central adenoid. The child was evidently in perfect physical health and there was no history of hemophilia. The two tonsils were very easily removed, anterior and posterior pillars were not wounded. After removing the right tonsil, I remarked to my assistant that the tonsil was removed unusually successfully, that the cavity remaining was unusually deep and that I could see a small spurting point from the upper anterior face of the posterior wall of the cavity. The spurting point was small and was about the size of the vessels cut in a mastoid operation. I held a sponge against it for about three or four minutes and then, the bleeding having apparently ceased, proceeded to remove the adenoid. The last thing before I stopped the operation, I wiped out the right tonsil cavity and could see no sign of hemorrhage.

About three hours after the operation I received a telephone message from the hospital saying that they thought that I had better come at once. As I was in the middle of my office hours, I asked Dr. Powers to go around first, as he was nearer, and I followed as soon as

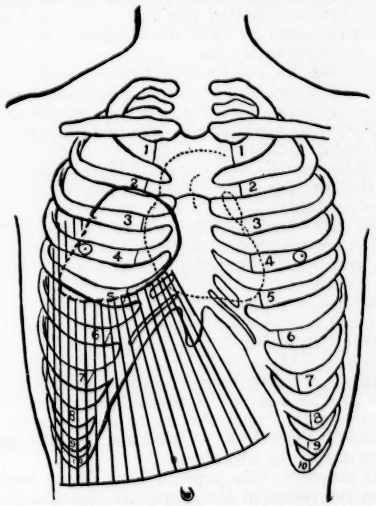
possible. He probably arrived there within five minutes and I within ten minutes of the first alarm. When I saw the child he was completely exsanguinated and the radial pulse could not be felt nor could I be sure that I felt the carotid pulsation. The hemorrhage had been checked on Dr. Powers' arrival by digital pressure of the right tonsillar cavity. This was kept up until a tonsil clamp could be procured and placed on (perhaps half an hour) and it may be known that the child was in pretty bad condition when I say, there was absolutely no resistance made to putting a gag in the mouth and holding three fingers firmly against the side of the tonsil space during all this time. A pint of salt solution was given subcutaneously in the breast and two pints by rectum soon afterward. The child's pulse began to come back after the first subcutaneous infusion and could be counted at 160. Dr. Powers thought he had previously counted it at 200, but I could not be sure of this. Later on it fell to 140.

The tonsil clamp when applied was kept on about eight hours and when removed there was a large dark blood clot at the fossa. No further hemorrhage resulted. The child was completely prostrated and did not leave the hospital for ten days, during all of which time he ran a temperature from 100 to 102. He was extremely pallid and the throat was more septic than any throat I have ever seen. The child did not recover from the operation sufficiently to go to school for six weeks.

The nurse said that during the three hours between the operation and first alarm she had noticed no more than the usual hemorrhage until the child began to vomit and vomited fresh blood. The hospital where I performed the operation was within three blocks of my office. Had it been much further off, I do not question the case would have been dead before it could have been reached. It certainly was more exsanguinated than any case I have ever seen.

CASE II. About four months afterward, I operated on a twelve-year-old girl in Auburndale, again with large nonadherent tonsils and not having learned wisdom by experience began with the same technic of operation. Tonsils easily removed; pillars not wounded. The nurse in attendance said that the first sign of hemorrhage was observed about two hours after the operation. After a good deal of telephoning she succeeded in getting Dr. Hammond out about three hours after the operation, and I arrived about four hours after the operation. The hemorrhage, according to the physician who was one of large experience in throat cases, was very profuse, filled the throat so that she was unable to tell which tonsil it came from, consequently, it was impossible to apply the tonsil clamp. The family showed Dr. Hammond a basin which contained about a quart of blood, but they and the nurse said it did not equal all the girl had vomited. The hemorrhage had checked itself before Dr. Hammond arrived. The girl was pallid and the pulse was 130 to 140; she had sighing respiration and a good deal of faintness and complaint of thirst. A large clot of blood could be seen in the space of which one of the tonsils had been removed. The case was watched for about eight hours and then transferred in an ambulance to the Newton Hospital, not far away. She was unable to stand up and remained in bed for about eight days after the operation, but recovered perfectly.

It seems to me that these two cases which are being reported should be placed upon record. One lesson which I certainly learned from them is that I should never again remove the tonsils under any consideration unless the case is willing to come in town and be near my office for twenty-four hours after the operation. The first case would undoubtedly have died had it been anywhere but near my office. The second case would unquestionably have died before help could have reached it, if it hadn't been that the hemorrhage ceased itself. In addition, I should advise No. 5 steel wire in threading the tonsil snare.



CONGENITAL DEXIOCARDIA.

BY W. F. DOOLITTLE, M.D., CLEVELAND, OHIO.
From the Cleveland City Hospital.

THE following described case of unusual anatomical interest has recently come under my observation.

Mr. F. N. G., aged forty-one, born in the United States, white, mechanic, applied for treatment on my service at the Cleveland City Hospital, May 31, 1907. He complained especially of "a swelling with pressure and distress" in the epigastrium, also of "swollen limbs below the knees, shortness of breath and loss of strength."

The routine physical examination showed among other things a very marked funnel-shaped breast, at whose apex at midsternum a loud diastolic murmur is

heard. By percussion and auscultation the heart was made out, lying entirely to the right of the sternum, which bounded it on the left, as shown in the accompanying diagram. The second rib marked its upper limit. The apex-impulse of the heart was located in the fifth interspace just inside the mammillary line, marking the heart's axis downwards and to the right. A movable dullness in the right axilla reaching to the third interspace obscured the outer border of the heart. Its lower bounds were also hidden by similar dullness fading into the liver flatness, which extended to within an inch of the umbilicus in the median line. The pulse

rate was irregular at 115 to 120 and quite arrythmic. A capillary pulsation was easily demonstrated in the index finger, and the poorly sustained radial pulse on elevation aided in confirming the diagnosis of aortic insufficiency with broken compensation.

As it is not the purpose of this article to dwell on the pathology, it may be dismissed with the statement that rest in bed, moderate doses of digitalis and aspiration of 1100 cc. of serous fluid from the right side of the thorax brought prompt moderation of the symptoms. The orthopnea disappeared, the character of the pulse improved and its rate was at 80 in a few days. Following the tapping the lower border of the liver returned nearly to its normal limits and the epigastric distress then ceased.

However, the removal of the fluid did not alter the area of cardiac dullness. Inquiry of the patient revealed the following interesting facts relating to this transposed organ:

The position of the heart on his right side was noted at his birth by the physician, and the mother's attention was called to it. The patient has a twin sister whom, as a child, he very closely resembled in features, but her heart is normally located. Each of their parents was a twin, but their hearts are said to have been on the proper side. My patient has a wife and a twin son and daughter. The children are about four years old and look just alike. While the girl's heart is placed as usual, the boy's heart is, like the father's, on the wrong side of the chest. Some years ago the wife miscarried a pair of twins at the seventh month. Unfortunately no anatomical examination of the fetuses was made as to the heart's position.

It is of interest that the patient's twin sister also has a pair of twins (boy and girl), four years old, residing in a distant city, who are said to look just alike; but, in their case, my patient "thinks" their hearts are on the left side.

The patient is slightly under medium height, well nourished and claims unusual strength and health until recently. As a child he was naturally left-handed — a functional peculiarity noted in other cases of transposed heart. At school he was encouraged to use the right hand more and so became ambidextrous.

The percussion tone at the apex of the right lung is higher than that of the left — a fact which might be accounted for (in case the lungs are transposed) by the pressure of the right hydrothorax. Still, the character of the sign is but little altered since aspirating.

In conclusion, attention may be called to the following:

Dexiocardia, a local transposition, is comparatively rare and should not be confused with the not uncommon cardiac displacement due to disease. Blodgett states that in the examination of 20,000 recruits for the German army only two cases of dexiocardia were encountered.

The condition is said to have been very exceptionally noted at birth, and generally was not suspected during life.

Ballentyne, in his recent excellent work on "Antinatal Pathology and Hygiene" (1906). states that there had appeared no evidence of the transmission of this anomaly by heredity. He cites E. Rogi's cases of brother and sister as being quite unique as an instance of family tendency.

While dexiocardia is said to have been noted twice the number of times in males that it has in females, which may be accounted for by military and insurance examinations, yet many cases may indicate a tendency for transmission, under certain circumstances, in the male line.

Aristotle was the first to describe transposed organs. It is of further historic interest that the wife of Henry IV of France (mother of Louis XIII) had the heart to the right of the sternum.

Several theories as to the cause of this anomaly have been advanced. However, Ballentyne states that the inverted position of single organs is not to be regarded as directly related to the causes of situs transversus viserum (due to malformation of the germs, Winslow), but is ascribed to local anomalies in development, which belong to a later stage in embryological formation.

AN ABDOMINAL LESION SIMULATING CANCER.

BY BENJAMIN B. CATES, KNOXVILLE, TENN.

In the latter part of March, 1907, I was called in consultation by Dr. J. H. Wilkerson to see Mr. George Dunlap, who was suffering from some obscure trouble in the left lower quadrant of his abdomen.

I obtained the following history:

Mr. Dunlap is a merchant, fifty years old, large-boned, and inclined to be slightly obese. He relates he has always been healthy; but within the last six or seven years has been growing constipated to such an extent that he has had to use purgatives constantly.

Mr. Dunlap further says that on the twelfth of March, 1907, he retired at night as usual, remarking to his wife he "felt better than he had for months and months."

About 1 A.M. on the following morning he was awakened by a sharp pain in the left lower quadrant of his abdomen. The pain became so severe he sent for Dr. Wilkerson, who relieved him by a hypodermic of morphine and a purgative.

However, Mr. Dunlap did not feel inclined to go about his business, and was kept under the constant attention of Dr. Wilkerson.

After a few days of observation, Dr. Wilkerson suggested I be called in to consider the advisability of an operation.

When I saw Mr. Dunlap he was lying in bed, not suffering much pain; he had no inclination to move about. His pulse and temperature were normal, though Dr. Wilkerson said when he first saw Mr. Dunlap he was having fever. His abdomen was not distended.

Superficial palpation showed a slight degree of resistance on the left side, which on deep pressure in the left lower quadrant caused him to flinch and cry from pain.

From a digital examination of the rectum I could discover nothing abnormal, except, four or more inches from the anus I fancied there was a slight bulging of the bowel on the anterior surface. Anyhow, pressure against it caused pain.

With this history and examination I was not satisfied in my mind as to the pathology of the case and made arrangements to see Mr. Dunlap again in a few days. This I did without forming any well defined opinion other than that it was a case for operation.

I, therefore, suggested an exploratory operation, which was accepted.

Accordingly he was removed to the hospital of the Tennessee Medical College, and was operated upon April 4, 1907.

Thinking perhaps I might have an incipient cancer

of the rectum to deal with I made a long incision parallel to and above Poupart's ligament. When I got into the belly I found the pelvic cavity filled with small bowels and so adherent to every thing that I abandoned the first incision for the time being, and opened the abdomen in the middle line, in order that I might have a better field for operation. The small bowels filled the pelvis and hid the sigmoid and rectum from view. In sponging the adhesions apart, I broke into a pocket of foul-smelling pus on the left side of the sigmoid and rectum. I estimated there must have been half a pint of this pus.

While the pus had a foul fecal odor, I did not find any fecal concretions, nor did I find any communication with the bowel.

I then placed the patient in the reversed Trendelenburg position, placed gauze around the bowels, so as not to infect the general peritoneal cavity, introduced cigarette drains from both wounds down to the pocket of pus and closed the wounds down to the drains.

The subsequent steps of the treatment followed was to keep the patient in Fowler's position and to give daily enemas of normal salt solution by Murphy's plan. The patient made a slow but sure recovery, without developing any permanent fecal fistula, though for about a week after the operation the discharges had a decided fecal odor.

The pathology of this case was unique to me, and I was at a loss to account for it, because I had never seen a similar condition in the operating room, nor could I find anything in the literature in regard to it. Hence I called it acute periproctitis, and acute perisigmoiditis.

The etiology of this case was interesting, and in seeking for a cause I accidentally learned from the patient that a few years ago a traveling quack came through the town delivering lectures on "health and how to preserve it." Among other things he taught that people, in order to aid digestion and cure constipation, should eat every day a teaspoonful of sand. So this good man was induced by some friends to eat sand for constipation. This, I thought, may have been the secret of the trouble. The sand might have lodged in some of the folds or pockets of mucous membrane of the sigmoid or rectum and caused ulceration, secondarily setting up suppuration around the gut.

Since writing the above report of my case I have read very interesting reports in *Surgery, Gynecology and Obstetrics* for July, 1907, by Drs. W. J. Mayo, of Rochester, Minn., and George Emerson Brewer, of New York, on "Diverticulitis of the large bowel," that throw a good deal of light on the pathology of my case.

THE CHOLERA SITUATION IN RUSSIA. — According to press dispatches from St. Petersburg, Oct. 31, the latest official cholera statistics for the week ending Oct. 22 show that the epidemic is now being checked with the approach of winter. There were 1,009 new cases reported and 416 deaths were recorded. More than half the number of cases, 569, were in Kiev and Volhynia provinces, where the winter is belated. There were only 103 cases in the four southern provinces and 75 in the five provinces of the Middle Volga region.— *New York Med. Jour.*

Medical Progress.

PROGRESS IN SURGERY.

BY J. G. MUMFORD, M.D., BOSTON.

RESULTS OF THE OPERATIVE TREATMENT OF BREAST CANCER.

(Concluded from No. 19, p. 640.)

HALSTED, more than other writers, distinguishes degrees of axillary involvement, giving four groups of cases depending upon the extent of involvement: (*a*) base of axilla only; (*b*) base and mid-axilla; (*c*) base, mid-axilla and apex; (*d*) veins intimately adherent. He shows how groups *b*, *c*, and *d* are much the most difficult and serious and lead with considerable certainty to an involvement of the supraclavicular region, and he finds this region above the clavicle the seat of disease in a surprisingly large number of cases. Of his 232 cases the neck operation was done in 119; while of the remaining 113 cases, in which the neck operation was not done, 44 were operated upon subsequently. Halsted finds microscopic involvements of the neck glands in great numbers of cases which show no palpable evidence of disease in that region. For this reason, he insists upon the neck dissection in all cases in which the axilla is involved beyond the base. He lays down the following rules: the surgeon should perform the neck operation, "barring, of course, special contra-indications: (1) in all cases with palpable, operable neck involvement; (2) when the apex of the surgical axilla is involved. When mid-axillary involvement is demonstrable at the operation, special implication is almost certain, and hence, (3) in these cases also the neck should be typically cleaned of its lymphatics, as high, at the very least, as the bifurcation of the carotid.

"We find ourselves for the past two years again performing the neck operation in most cases. We omit it in hopeless cases."

As evidence that involvements of the neck do not imply necessarily a hopeless condition, Halsted cites 40 traced cases, in which cancer was found and removed from both neck and axilla. Four of these cases survive the three-year limit, showing us positively good end-results in 10%.

On the other hand, Greenough, and most of the other speakers, conclude from their studies that cancerous glands above the clavicle practically contra-indicate an operation for radical cure. Of 38 cases reported by Greenough, with involvement and removal of the neck glands, none survive. Willy Meyer does not favor the neck operation and finds none of his neck cases alive after a five-year limit. Ochsner dissected the neck seven times in 78 cases. His seven neck cases are dead. The studies and conclusions of these three speakers, however, are by no means as exhaustive and satisfactory as Halsted's, nor is their experience with neck involvements as extensive.

L. S. Pilcher supports Halsted's views in an entirely interesting and convincing paper. The former surgeon has made a painstaking endeavor

to dissect the neck in all advanced cases which have come under his hands during the past ten years, and his success in eliminating completely the disease is excellent. So long ago as 1900 he reported a series of ten cases, from which he had removed cancerous neck glands, with a resulting immunity of 33.3% after three years. He now reports a further interesting group of 18 cases. Taking all of his reported cases from which demonstrable cancerous growths in the neck were removed, Pilcher shows the surprisingly low end-mortality of 64%, so far as now appears,—the best and most encouraging end-mortality statement dealing with these supraclavicular cancer nodes that has been recorded up to this time. He reminds us further of the dense, deep cervical fascia which renders difficult a detection of cancer nodules until they have attained a considerable size, and insists strongly on the importance of the surgeon's recognizing the probability that the supraclavicular glands are infected in every case of extensive cancer of the breast.

Many of the speakers urged again the vital importance of an early *diagnosis* in all cases of breast tumor, and a few had something new to contribute to the subject. All intelligent practitioners now agree that every tumor of the breast should be seen by a competent surgeon, though unfortunately we know that great numbers of breast tumors remain undiagnosticated until the complete operation is hopeless. Vander Veer dwells upon what he calls "the pre-cancerous state, from the nervous condition of the patient," and relates an interesting case in illustration of his contention that frequently patients are convinced of the imminence of a malignant growth long before the surgeon, while often the outcome justifies the patient's forebodings. Vander Veer would not disregard this anxiety.

Halsted finds a great interest in determining the early diagnosis of cancer. Physicians should remember that more than 80% of all breast tumors are malignant, so that the presumption of cancer is ever present, and should warn the optimist when examining a painful or lumpy breast, even in a young woman, that the burden of proof rests upon him to show that the disorder is not cancer. Says Halsted, "It well repays the experienced surgeon to spend perhaps an hour in the examination of certain breasts." We are seeing constantly "smaller and still smaller tumors, cancers which give not one of the cardinal signs." He reminds us of the adenoma in a transitional stage, but more difficult still the tiny retro-mammary adeno-carcinoma, or the colloid carcinoma, in a breast covered with one or more inches of fat. "If in such a case there should be no shortening whatever of the trabeculæ the diagnosis could hardly be made." "But given even very slight shortening of the trabeculæ from tumor to skin, this fact might be determinable by making both breasts take the widest possible excursions on the chest wall under the skin, the faintest conceivable trace of a difference of the two sides, in a minor pectoral crease, for example, may suffice for the diagnosis." "Frequently there is no sign but the almost imperceptible suggestion of pull, which, when the faintest possible, is of course elicited by dislocation in one direction only. This sign, however slight, is all that is needed for the diagnosis." The surgeon must manipulate both breasts in making this test, in order that one may serve as a control. It is interesting to read Halsted's statement that to him, with his enormous experience, the extreme possibilities of the test were not fully realized a decade ago, and that each year it developed a little in refinement; and he remarks that it should impress the uninitiated to witness the ability of the demonstrator to diagnosticate with the fingers, through considerable fibrous tissue, hardly visible cysts yielding on puncture the tinest fraction of a drop. Halsted dwells also on the importance of determining the size of the involved breast relative to the other breast, and of noting most carefully the relative amount of uninvolved mammary gland remaining.

"Given a carcinoma, say, one half or one quarter as large as the palm of the hand, if this tumor has grown not at all, or little, at the expense of the breast, the prognosis is relatively good, for the tumor in such case is quite surely of a definitely adenomatous type and not of the scirrhous variety." Halsted holds that a scirrhous cancer represents only a part of what has existed, for the struggle against the cancer cells resulting in fibrous tissue production is not always futile, and when the minute foci of cancer epithelium have been destroyed, the new fibrous tissue may in part be absorbed also. As a result the scirrhous disease may be active, and metastasis take place a long time before the visible or palpable tumor is developed. We have seen how cancerous glands in the axilla may exist without obvious breast cancer, though later there developed a malignant tumor in the corresponding breast.

These remarks and reflections of Halsted demand the serious consideration of surgeons.

The subject of *prognosis* is probably the most important single element in this discussion, and we know how the histological character of the special tumor bears immediately on this subject; as Dennis says, the type of the cancer seems to have an influence on the prognosis greater than the now accepted radical operation. I have already referred to this matter in this writing, and incidently have pointed out the significance of glandular involvements as bearing upon the prognosis. Furthermore, Oliver states that the location of the primary growth is significant since "central growths and those located in the lower third of the base give a much larger percentage of recoveries than do growths located elsewhere." But there is no certainty in prognosis, even prognosis of evil, for, as Oliver states further, that matter in an individual case will always remain a doubtful question. "Seemingly favorable cases sometimes progress to a fatal termination, whereas one is sometimes pleasantly surprised by having an unpromising case go on to recovery."

Physicians are wont to ask us how much disability results from extensive mutilating operations on the breast. It is interesting to hear the unanimity with which the Washington debaters assert that the disability is slight. For instance, Greenough states that out of 53 patients interrogated 26, or about half, reported perfect use of the arm; 20 reported good use; 4 fair use, and 2 only "a little" use, while one described the arm as "stiff." That is to say, 50 patients out of 53 had serviceable arms after the subsidence of the initial shoulder lameness, which is so common. About one third of his cases had some swelling of the hand or arm, but this interfered little with the use of those members, and was transient in most of the cases. Ochsner bears similar testimony, stating that swelling of the arm was troublesome in but 10% of his cases. Jonas speaks of frequent swelling of the arm, but no permanent impairment of its use, while Oliver reports lymphedema of the arm in five of his 35 patients. Says Greenough, "It is probable the swelling of the upper arm is to be regarded as the direct result of the removal of the axillary lymph trunks; but swelling of the hands and fingers may probably be attributed to cicatricial pressure upon the vein. It is reassuring, however, to find that swelling of the arm occurs so commonly in cases without recurrence, and that it is not to be regarded necessarily as evidence of axillary recurrence."

Most of the speakers decline to accept an arbitrary time limit of three years as representing cure of the disease, and this feeling is expressed by Halsted, when he says that we should demand as proof of cure in those most difficult cases with involvement of the neck, that the patient live at least five years after the operation. Even in cases which suffer recurrence surgeons find that the recurrence often comes late. Oliver says that the average duration of life after operation (in fatal cases) is twenty months, according to his experience; the average time of recurrence being fourteen and one quarter months. Probably most surgeons will agree with Ochsner, who finds that about one half of the deaths occur within the first year. For instance, out of 43 eventually fatal cases, Ochsner reports 24 dead within a year, 30 dead within two years, and 36 dead within three years, the remaining 7 deaths being strung out over fourteen years. The statements of Oliver and Ochsner correspond quite closely with those of the other speakers, so that the surgeon should feel justified in strongly encouraging the patient who has survived the one-year limit.

The significance of the word *treatment* does not seem to appeal with entirely equal force to all operators, as one may gather from the quotations already given in this article. Greenough discourses upon four types of operations: *complete*, *semi-complete*, *incomplete* and *palliative*. By *complete* operation he means wide removal of the breast, both pectoral muscles, the axillary contents, and occasionally a dissection of the neck. We have seen that Halsted and Pilcher dissect the neck if there be cancerous deposits beyond the base of the axilla. All of the other speakers practically agree with Greenough in his definition of a complete operation. But it is needless to dwell further on this well-ventilated topic.

All surgeons appear to agree also in the proposition that wide areas of skin invariably should be removed; but one would be interested to watch their individual practice for, from the words of the speakers at the symposium, it is hard to believe that their conceptions of wide skin areas correspond. It seems that few surgeons remove so small an area of skin as to allow of direct suture of the wound. Halsted dissects out a great disk and covers in the raw surface with skin grafts, while others employ the plastic operations of Warren, Willy Meyer and Mixter. Greenough states that in his list of complete operations many of the wounds were *sutured directly*, with a resulting end success of 11.7%; while, in another large series of wounds closed by *plastic* flaps, 19.4% were successful. Halsted remarks that he should not care to say, "Beware of the man with the plastic operation," and endorses a statement that the operator whose duty it is to close the wound should not be intrusted with the planning of the skin incision. However, he does not regard the use of plastics as entirely taboo, but asserts positively that no surgeon should invariably plan his operation with a plastic in mind.

A careful reading of these papers impresses one with the fact that a great many surgeons interpret the words *complete operation* to correspond with their personal conception of the extent of disease in the individual case. Cabot says, "If the disease had infected many lymphatic glands it was sure to recur, even after a thorough removal of *all the muscles and axillary contents*." "In case 12 the nodule in the breast was small and so situated in the center of the gland that I felt safe in leaving the pectoral muscle. . . . Since that experience I have removed the muscles in all cases." Says Dennis, after vigorously endorsing the radical operation in suitable cases, "The element of time should be seriously considered, since the performance of any operation which requires the patient to be under an anesthetic for four or five hours is attended with a risk, which should, if possible, be obviated."

The veteran Vander Veer, commenting upon his own most favorable list of cases, remarks, "I would say that in the cases that are reached early I am not yet convinced that the very radical operation of removal of the pectoral muscles is called for, but we cannot be too emphatic in impressing on the younger men the necessity of careful examination and dissection of the axillary spaces."

Jonas sums up well the average practice of the best surgeons, when he states, that "no modern surgeon would have the temerity to stop short of a complete removal of the entire breast and axillary contents in the very early cases, and in later ones remove, in addition, both pectoral muscles and the fat from the supraclavicular

triangle"; while Jacobson has "employed the incision suggested by Dr. Halsted and has followed his technic, except as to the supraclavicular glands, in all cases. The latter step has only been undertaken when there has been apparent invasion of the neck. The axillary space has been thoroughly cleaned out, the pectoralis major and sometimes the pectoralis minor have been removed."

Contrast the foregoing statements and their associated evidence of good and improving end-results with the following brief profession of faith by Halsted: recognizing that extension, the most rapid, takes place "beneath the skin along the fascial planes, we must remove not only a larger amount of skin and a much larger area of subcutaneous fat and fascia, but also strip the sheaths from the upper portions of the rectus, the serratus magnus, the subscapularis and at times from parts of the latissimus dorsi and the teres major. Both pectoral muscles are, of course, removed.

"A part of the chest wall should, I believe, be excised in certain cases, the surgeon having in mind always that he is dealing with lymphatic and not blood metastasis, and that the slightest inattention to detail, or attempts to hasten convalescence by such plastic operations as are feasible only when a restricted amount of skin is removed, may sacrifice his patient.

"It must be our endeavor to trace more definitely the routes travelled in the metastases to bone, particularly to the humerus, for it is even possible in case of involvment of this bone that amputation of the shoulder joint, plus a proper removal of the soft parts, might eradicate the disease. So, too, it is conceivable that ultimately. . . amputation at the hip-joint may seem indicated."

In comparison with the splendid radicalism of Halsted all lesser operations pale, yet they are seriously to be considered if we regard published statistics only. Greenough reports 75 *semi-complete* operations, with an end-mortality of 75%, as contrasted with his end-mortality of 84% for *complete* operations. (By semi-complete he means his complete operation, done without disturbing the pectoralis minor.)

He reports 85 *incomplete* operations, with an end-mortality of 75%. (In the majority of these operations, which were done more than ten years ago, the pectoral muscles were not removed; in some the whole breast was not taken, and in others the dissection of the axilla was incomplete.)

Furthermore, Greenough reports 56 *palliative* operations, with an end-mortality of 93% only.

The reader will remember that Greenough's tables deal with cases running back thirteen years. We must not take courage too eagerly over the good results of his incomplete operations. Those patients of his may thank fortune that at the time of their operations the disease was still in its earliest stages.

Methods of treatment for cancer other than operative methods find a certain amount of qualified favor among surgeons. Most of the debaters have something to say about the x-rays, though none of them describe accurately their manner of using them. Cabot feels that occasionally the x-rays have checked and delayed the growth of inoperable cancer, but he does not feel that they are positively curative. Willy Meyer regards the x-rays as valuable in the immediate after-treatment, and urges every patient to submit to a six or eight weeks' course as soon as healing has been accomplished. He reports one case, for which he gave a bad prognosis at the time of the operation, but in this case faithful, intermittent use of the x-rays has had a most gratifying result. There has been no recurrence in four years. Of course, a single case of this kind is not convincing. Ochsner advises the use of x-rays systematically after all operations for breast cancer and believes that he sees their benefit. Jacobson also uses x-rays in the same fashion. On the other hand, Vander Veer has seen little permanent good result from the use of the x-rays, except that undoubtedly in many cases they relieve pain, and sometimes delay the activity of the growth. In this connection one recalls Crile's enthusiastic endorsement of x-ray treatment after the removal of cancer of the neck. His method is to leave the wound wide open and to project the rays directly into its granulating depths, employing the treatment every other day for several weeks, and so vigorously as to keep up a mild dermatitis in the vicinity of the wound. We encounter an interesting paradox when we contrast these facts with the experience of those well-known x-ray workers, who have contracted malignant skin disease from long continued exposures to the rays.

Halsted again reminds us of the occasional value of caustics in the treatment of cancer, and points out that regional recurrences after incomplete operations may be delayed by the use of chemical or actual cauterization. Caustics seem to check cancer permeation of the surrounding tissues, and Halsted states that all incomplete operations for cancer should, when possible, be made with the Paquelin or actual cautery. Other surgeons, notably the Mayos, endorse this view and practice.

If one may epitomize the combined teachings regarding treatment, of the Washington speakers one may say that cancer of the breast should be removed with a great skin margin; with a wide dissection of adjacent fat and subcutaneous tissue; with excision of both pectoral muscles; occasionally with stripping the fascia from the numerous neighboring muscles; with thorough cleaning out of the axilla, and when the axilla is involved beyond its base, with dissection of the neck as far as the bifurcation of the carotid. Palliative operations should be performed if possible with the Paquelin cautery, and in all cases the wounds should be treated subsequently with the x-rays for at least six weeks.

In conclusion, so numerous are the figures and so prolific the writers and speakers that one could pile up great numbers of familiar or curious facts, but the main points of the story have been

brought out, and we may sum up the discussion in somewhat the following fashion:

The speakers in Washington dealt with 1,194 cases, and an end-mortality of 56.63%, including all varieties of subjects, all varieties of breast cancer, patients of various ages and growths of various development. The case surviving longest *without* recurrence is a patient of Dennis. Twenty-nine years have passed since her operation. The patient surviving longest *with* recurrence was attacked secondarily in the twenty-second year after her operation.

Of the 1,194 cases reported, 518 are now alive and in good health, after more than three years have passed since their operations.

Operations varying greatly in extent and severity were done by these speakers — operations varying from palliative to extensive mutilating dissections.

Handley's explanation of the permeation of cancer meets best our understanding of the conditions of spread, metastasis and recurrence of the disease.

Extensive axillary involvement implies supraclavicular involvement, and calls for extensive dissection in a great number of cases. Cancerous glands in the neck do not point necessarily to a hopeless condition.

Palliative operations should be executed with a Paquelin cautery so far as possible.

Recurrence in the scar is becoming less common as we appreciate increasingly the importance of removing wide disks of skin. Internal metastasis is most common in the lungs, mediastinum, liver, spine, brain, humerus and, occasionally, the femur.

Even pessimists will admit that these results, representing the work of widely scattered groups of surgeons, show a great advance over what we knew when this generation was ten years younger.

Reports of Societies.

NEW ENGLAND OTOLOGICAL AND LARYNGOLOGICAL SOCIETY.

MEETING HELD AT THE MASSACHUSETTS CHARITABLE EYE AND EAR INFIRMARY, JAN. 18, 1907.

THE President, DR. A. COOLIDGE, JR., in the chair.

DR. E. A. CROCKETT read a paper on

TWO CASES OF HEMORRHAGE FOLLOWING TONSILLOTOMY.[1]

DISCUSSION.

DR. F. P. SPRAGUE, of Providence, read a report of some secondary cases.

One patient was operated on under ether, the ridge, the adenoids and both tonsils were removed. Everything went well until the fifth day. On the fifth day after the operation, in the night, as usual, they telephoned for me to come to the house as the patient was having a severe hemorrhage from the right tonsil. I went and in an hour or two I was able to check the bleeding. In two days there was another hemorrhage, which was more easily stopped than the first.

These are the only cases of secondary hemorrhage that I have ever had, and naturally, every time I see an adult tonsil to be removed, I have a fear of the fifth day. If I can get over the fifth day, I feel quite safe.

In this case, the reason it took so long to stop the bleeding was because every time the patient swallowed the clot was torn away from the surface and the bleeding immediately followed.

As regards antisepsis of the throat, I had this throat sprayed every two or three hours, from the time of the operation until after the hemorrhage, with Dobell's solution. Although this throat seemed perfectly clean, of course there must have been some infection. Certainly, I think some precautions are necessary.

If a person comes to me with hypertrophied tonsils and adenoids, and looks like a thin-blooded individual, I try to have that patient better nourished and do what I can to improve the quality of the blood before anything is done in the way of an operation. After the operation, I take the precaution to paint the throat thoroughly with glyceride of tannin, and it seems to me that this has been a help.

In some cases, if there is very much bleeding at the time of the operation, I use cracked ice and hold it in the body of the tonsil for a few moments after the operation. Following the operation, for the first day, I do not allow the patients to have anything even warm; I keep them on cold milk and ice cream and cracked ice.

Ice cream is always grateful to the children, almost everybody likes it, and it certainly has a beneficial effect in keeping the blood vessels contracted. In grown people, I do not allow the patients to have hard crusty things, nor hot foods, for three or four days following the operation. It seems to me that is some help in the preventing of hemorrhage.

I do not see how much better off we are in taking out a piece of the tonsil, to see whether it is going to bleed or not. In this case that I reported, the woman was twenty-seven years old at the first operation, and thirty-six at the next, but the tonsils were as soft as we usually find in a child of a dozen or fifteen years of age. If a patient comes to me, and I get a history of repeated attacks of quinsy sore throat, I leave that tonsil alone because I think we stand a pretty good chance of getting into trouble by cutting such a tonsil.

After we get the hemorrhage, various methods are used. I have a clamp I carry in my bag all the time. I hope that I shall never have to use it.

I had one case where there was a hemorrhage from the anterior pillar, where the anterior pillar became engaged in the tonsillotome, and although it only chipped off an eighth of an inch, it bled quite profusely for some time. The patient was twenty-eight years old.

DR. J. P. CLARK: I have been very much interested in the reports of these cases of Dr. Crockett's and Dr. Sprague's, and it seems to me rather strange that removing the tonsils as thoroughly as we do nowadays, that we do not hear more of hemorrhage. I want to take this opportunity of reporting the only case I have had of secondary hemorrhage in a child. This occurred last spring, in a little girl of seven years of age, from whom I removed adenoids and tonsils. There was nothing remarkable about the operation, except that I made a note that the right tonsil was larger than the left, and that in removing the left, the hemorrhage was rather freer than usual. I heard from her every day, and on the fourth day about two o'clock, I received a telephone message from the parents saying that, about the middle of the night before, the child had waked up very much terrified, and had vomited up a large quantity of bright red blood, and had been spitting up blood ever since, and asked if they should bring her in to see me. Of course, I was very much surprised that they

[1] See page 661.

had not notified me before, and I said I would come out at once. The father came for me in his automobile, and thus I got to the house within a very short time after being notified.

I found the little girl with a bowl in her hands, spitting up blood. She was lying in bed, pulse 140, very nervous, and would not let me look at her mouth at all, but I got a sufficiently good view to see that the blood was coming from the left tonsil.

There seemed to be nothing to do but etherize her. I sent for Dr. D. Crosby Greene, Jr., to assist me, and for the family physician to give the ether. I found, on examination, that the blood was oozing quite freely through the remains of the tonsil. With a curved needle and catgut, I took two stitches through the posterior pillar, under the base of the tonsil and out through the anterior pillar, bringing the pillars together over the bleeding tonsil; after tying the sutures the bleeding stopped completely. During the operation, the child vomited about a pint of bloody fluid. She was put to bed. The pulse was then about 200, as nearly as could be counted. During the following night she was given two or three enemata of salt solution. She was kept in bed for ten days, and made an uneventful recovery.

The instruments used to remove the left tonsil had been a tonsillotome and a tonsil punch. While the sutures were in the throat, the voice was somewhat nasal, as their presence interfered with the motion of the soft palate.

Dr. Kittredge: Is there any special needle holder that you use?

Dr. Clark: I used an ordinary needle holder in this case.

Dr. T. A. DeBlois: I dare say Dr. Farlow recalls the celebrated case of Dr. Lefferts, of New York, who had to take up an artery and tie it in the mouth. He was able to locate it, pick it up with the forceps and tie it.

I had a case, myself, which drove me away from tonsillotomy for several years. I cut off both tonsils, and the woman bled for an hour and a half, and finally, when she fainted and rolled off the sofa, why then, she stopped bleeding.

In the labors of the medical inspectors in the public schools, where the children are sent to the hospitals by scores, for the extirpation of the tonsils and adenoids, one half of the patients will have tonsils to be removed together with the adenoids. We have been doing this for several years, and we have, to the best of my belief, had no trouble with hemorrhage with tonsillotomy, whether with the Leland knife or guillotine. Our procedure is always the same, adenoid, tonsil or anything else; we always scratch with the sharpened finger nail after cutting. It is a good thing in adenoids to clean out the little fossa of Rosenmueller with the finger nail, and it certainly tends to arrest hemorrhage, just as it does in obstetric cases. We follow that procedure with the tonsil cut off with the tonsillotome; we scratch and they bleed very little, and I suppose we have been doing this in these large institutions, 20 to 30 a day, for about five years, and I think that Dr. Vogel will agree with me, that we have never had a case of severe hemorrhage at the hospital.

Dr. F. L. Jack: I have seen only one case of alarming hemorrhage after removal of the tonsils. I did not operate myself, but was called in on account of the bleeding. The operator had removed a small portion of the anterior pillar, which contained a good sized artery. The child was etherized, and the artery seized with a pair of long forceps. I have seen a moderate hemorrhage at the time of operation, but never a case of delayed bleeding.

The causes of hemorrhage are apparent, but no one has enlarged upon the best method of arresting it. Unless the patient is etherized one cannot keep him still or open the mouth to see anything. Therefore, it would seem as though ether were necessary. Sewing the pillars together is a very difficult thing to accomplish.

I always carry with me a large hemostat, one blade of which exerts pressure on the tonsil and the other on the neck. The handles are removed, and the instrument left in the mouth.

Dr. W. S. Boardman: A patient came to the Boston Dispensary from Lawrence. It seemed advisable to remove his tonsils and I took off one with a snare, when an artery spurted and became very troublesome. The fellow kept his mouth open, while I wiped off the surface, found the spot and applied a hemostat. He went to the City Hospital over night, and came back to the dispensary in the morning, but did not care to have the other tonsil excised.

I do not know how long they kept the hemostat in his mouth. It seems to me that we should find out whether the hemorrhage is from an oozing surface or an artery, and consider whether a hemostat or the clamp, Dr. Jack spoke of, can be better applied. A bit of cotton or gauze wet with a solution of gelatin and applied to bleeding tissue acts well, and I have often found that gelatin, locally applied, helps to clot blood in a short time. I think the old remedy of applying compresses wet with compound tincture of benzoin, can be tried in some cases of hemorrhage from the nose, with success, but would not expect so much to result from its use in the case of excessive and obstinate hemorrhage, following removal of tonsils.

Dr. E. M. Holmes, of Boston: About two years ago I had a case, a girl twenty-one years old, from whom I removed a large tonsil. The operation was in the morning, and four and a half days after, there was this profuse hemorrhage. In this case, I used the curved needle and catgut suture, and instead of making two, I made five or six stitches about the pillars, forming a purse-string, drawing the tissues together in that way.

I used a Monks needle holder; it was not the easiest thing to do, but we had to do something, and this was entirely successful.

Dr. G. H. Powers, Jr.: Dr. Crockett told me over the telephone which side had bled at the time of operation, and I assumed that it would be that side when I arrived. I put on all the digital pressure I could bring to bear, until we could get a clamp there, from four to five minutes. After the hemorrhage had stopped, that clamp staid on until the next morning, eighteen or twenty hours, with, of course, great discomfort to the patient, but with no recurrence of the hemorrhage.

The patient was so exsanguinated that extreme measures were necessary — saline infusions, etc., after which he rallied very satisfactorily.

Dr. A. C. Getchell, of Worcester: I have had experience enough with bleeding to make me look upon every case with more or less anxiety, and watch the telephone carefully for two or three hours after an operation.

Dr. Jack has raised the question, What should we do?

My general plan, in the first place, is not to operate unless my patients can go immediately to bed, and stay there for a number of hours; in the second place, if there is bleeding, to keep them as quiet as possible with the head and shoulders elevated. I apply cold, in the form of ice, to the outside, and I think it is practical to get a good view of the area. If there is oozing, I think that peroxide of hydrogen, up to the full strength, is well worth using, locally, and if the pulse becomes rapid and weak I give a salt injection by the rectum. Of

course, if the bleeding is extreme, as it has been in one of my cases, I inject salt solution into the veins. The last resort of applying constant pressure or sewing together the half arches, I have fortunately never had to resort to. I carry with me a Douglass needle, which seems to meet the indications.

DR. F. P. EMERSON: It seems that the gist of all the remarks that have been made tends to show that this operation of tonsillotomy, even in the hands of the most skilful, is apt to be followed by serious hemorrhage. In these days when the general practitioner, as well as the specialist, is doing this operation, we ought to send out this warning. This is a surgical procedure which should be entered upon with every precaution, and these cases should be where they can be watched for twenty-four hours, especially in adults. There is no other field in surgery where we leave such a raw surface to practically take care of itself as in the adenoid and tonsil operation. In most cases, the hemorrhage comes on two hours after the physician has left the house.

As we are doing a more thorough and radical operation on adenoids and tonsils than formerly, it seems as though these cases should be put in a position where they can be watched, carefully looked after and treated surgically.

DR. HARRY BUTLER, of Bangor: I would like to report one case of primary hemorrhage at the operation. It was a little girl, fourteen years old. I used cocaine because she could be controlled more easily. I somewhat expected to get hemorrhage. One tonsil was rather a small one, and the other an extremely large one.

The history of the case was, that her family physician had for the past year been attempting to shrink the tonsils by various methods of treatment, preparations of nitrate of silver, galvanopuncture, etc. I made up my mind that the tonsil tissue was so hardened, and the walls of the blood vessels were so hardened, that they would not contract, so I removed the smaller tonsil first.

Then in the course of five or six days I removed the large one with a tonsillotome, and, as expected, got the hemorrhage. I removed it at about ten o'clock in the morning, and I tried all kinds of methods for the control of hemorrhage without result, finally controlling it by pressure with my fingers. I held my fingers, one on the inside and one on the outside, for about twenty to twenty-five minutes, then removed them and kept her very quiet in the office until about five o'clock in the afternoon; after which I accompanied her home and saw her safely placed in bed, and had no further trouble.

In this case, I think that the previous treatment was responsible for the excessive hemorrhage, and I think, as Dr. Farlow says, it pays us to try to determine beforehand what the prospect is for a hemorrhage.

I think that the act of vomiting is one of the methods which is very good in the control of hemorrhage, and I think in one of Dr. Crockett's cases possibly the stopping of that hemorrhage was due to the vomiting.

I always note the character of the blood at the time of the operation. In nearly every operation for adenoids or a tonsillotomy, while the child is being held forward, I notice the character of the blood, as it drops upon the white sheet. If it is watery, or light colored blood, I should naturally expect a little more hemorrhage, and one harder to control than if it is dark, thick blood.

DR. BOARDMAN: The point is brought up that, in operating, some tonsils are very apt to bleed excessively, while others do not, and are a lesser cause of anxiety. Suppose that you feared a hemorrhage, and it was necessary to operate, what would you do as a prophylaxis? It has been stated, and I believe I have proved, that the extract of the thyroid gland assists in helping the blood to clot, which is also true of chloride of calcium, so it does seem to me that we can prepare a patient shortly before an operation, and proceed to remove the tonsils in all safety.

DR. E. E. FOSTER, of New Bedford: There was an article recently in one of the German magazines, which reported a number of cases, and in all these cases (they were brought into this hospital where the writer was a surgeon) showed bleeding in the posterior pillar, and his theory was that these secondary hemorrhages were due to the action in swallowing. That is, the clot was torn away from the artery which, in many cases was quite good size, and in all these cases digital pressure was suffieient.

I had a patient which I operated on, two years ago, for chronic laryngitis, a man fifty years of age, treated for a year or two without success, but the only thing I could find was extremely large tonsils. I expected difficulty in removing them, but I was able to get a wire in back of his tonsils and hold it very easily. On the left side, however, there was a spurting artery, which at each heart beat would force a stream of blood across the throat; I was able to take it up and control it perfectly well, without any secondary hemorrhage whatever.

DR. A. COOLIDGE, JR.: I have read the article to which Dr. Foster refers. The number of cases reported was rather small, something like six to ten perhaps, and although all of those cases stopped by lateral compression in twenty minutes, still it seems to me that, under many circumstances, you would feel a great deal safer, if you could have a clamp on that tonsil which was in place and which was going to stay there for twelve hours.

DR. CROCKETT: It has always been my routine practice, in doing tonsils, to dissect off adherent ones with a Leland knife, and with the nonadherent put on an ecraseur forcep and make traction until I approach the pillar. In using the ecraseur, I just draw the tonsil out as far as I can easily, and then take a twist on the tonsil. I have always done that, and with many tonsils have had no trouble. I have always felt it safer to do that than to cut around the tonsil with a No. 5 wire.

I used the clamp on the first case about two o'clock in in the afternoon, and kept it on until ten o'clock at night; he was nearer dead than any one I have ever seen, and made no objection to anything; he was completely unconscious. I judged in this case, as well as the second, that it was impossible to tell which part of the tonsil was bleeding; the bleeding was so tremendous that it filled the throat, and it was quite impossible to tell where it came from, until the case was exsanguinated.

CARCINOMA OF THE AURICLE.

DR. F. L. JACK: I wish to show you the results in one or more cases of the radical operation, and one of amputation of the auricle for carcinoma.

The patient with the carcinoma is a man sixty years old. The growth was of two years' duration, and located on the upper part of the ear extending into the meatus a quarter of an inch. He was told the nature of the growth, and the only one thing to do, and he readily consented to amputation of the auricle. The entire auricle, with the exception of the lobe which was free from the growth, was removed. The lobe was then cut in halves, and the tissues removed close to the skin, and then this flap was carried above, and with a little adjusting the entire denuded surface was covered and the cartilaginous meatus stitched to this flap. Mattress sutures were successfully used. At the time

of leaving the Infirmary, the wound was entirely healed.

One other case, unique in my experience, of

FATAL HEMORRHAGE FROM CHRONIC SUPPURATIVE MIDDLE EAR DISEASE.

The patient was a small child who, a few hours after entering the Infirmary, had a sudden hemorrhage from the nose, throat and ear. It was so excessive that by the time the house officer arrived, the patient was dead. An autopsy was made by Dr. Verhoeff, who saved the temporal bone for a more careful examination, to determine the bleeding point. He feels quite sure that the hemorrhage occurred from the jugular vein. Hemorrhage following middle ear suppuration is unique in the history of this institution, and I can recall few reported cases.

EIGHTH ANNUAL MEETING OF THE AMERICAN THERAPEUTIC SOCIETY.

HELD AT WASHINGTON, D. C., MAY 4, 6 AND 7, 1907.

(Concluded from No. 19, p. 643.)

PHYSIOLOGICAL ACTION, ELIMINATION, AND THERAPEUTIC APPLICATION OF SODIUM CACODYLATE USED HYPODERMICALLY.

DR. SPENCER L. DAWES and DR. HOLMES C. JACKSON, Albany: Sodium cacodylate was introduced by Gautier, in 1899. During the next four years it was hailed as a desirable substitute for arsenic. In 1903, however, Fraser gave it its *coup de grâce*, for with one or two exceptions all English and American text-books deny the possibility of its having either physiological effects or therapeutic value when given hypodermically. The studies of Dawes and Jackson show that the drug has a distinct pharmacological action (being decomposed and eliminated as arsenates in the urine, feces and probably the sweat and breath), and has a toxic effect; the urine of the patients yields arsenates and reacts to Marsh's test. It also gives many of the therapeutic effects common to arsenic compounds. The authors set forth the experiments used to sustain this contention. Cases are also cited illustrating its therapeutic value. These include lichen ruber, psoriasis, eczema, anemia, Hodgkin's disease, chorea, gastralgia and neuroses. Of 45 cases reported, 34 were either entirely cured or much benefited; 11 were not helped, and 2 were apparently made worse.

DISCUSSION.

DR. H. VAN RENSSELAER, Albany, commended the paper as being thoroughly scientific. He was inclined to take a middle ground as to the value of the remedy. The advantages are that it can be used when arsenic cannot be given; in hysteria and nervous affections the hypodermic method in itself makes a distinct mental impression; the patient must come frequently for treatment and is thus kept under observation. Disadvantages are that the drug is expensive, and the patient must expend considerable time in coming for treatment. He thought it wise to try ordinary arsenic first, and if that fails fall back upon sodium cacodylate.

DR. DAWES, in closing, described the method of injection. It is injected intramuscularly in the buttock. A sense of exhilaration follows. There are few complaints of pain.

A RESUME OF THE PHYSIOLOGY OF THE KIDNEY WITH A VIEW TO THERAPEUTICS.

DR. V. E. HENDERSON, Toronto: Dr. Henderson concludes that Brown-Séquard's contention that the kidney has an internal secretion has lost rather than gained weight. The cells of the tubules undoubtedly excrete urates, hippurates, pigments, and possibly creatinin. They are permeable, and in man may excrete water, chlorides, phosphates, sulphates under stimulus, and under more abnormal circumstances dextrose. The urine leaving the tubules, though usually more concentrated than the plasma in salts and urea, under a rapid flow more nearly approximates it in salt composition, and may even become more dilute than the plasma. Filtration does not occur; it is rather a diffusion under pressure. He suggests that the term secretion as applied to the kidney be dropped. A theory may be advanced in the future based on the following facts: between the membrane and the substance passing through it some chemical affinity must exist; for instance, a membrane may exist such that water and salt may pass through it but not such a crystalloid as sugar; when the affinity is slight, in case of a dilute solution, though none of the dissolved substance may pass through, yet with a higher pressure it may do so; the osmotic pressure does not vary with the substance present or with the temperature; different membranes may allow different crystalloids to pass through but not the same crystalloids.

DISCUSSION.

DR. OLIVER T. OSBORNE, New Haven, commended the paper. A number of years ago we dropped the term "Bright's disease" and now speak of renal sufficiency or insufficiency. We cannot determine the pathological condition of the kidney by chemical means; patients do not necessarily die of kidney disease when albumin is present in the urine, and yet they may do so when none is present. We should make a more careful examination as to salt excretion in order to determine if possible what portion of the kidney is diseased. As to whether the kidney has an internal secretion, the affirmative position must be disproved. It is possible that the kidney forms an antitoxin. This is indicated by the fact that in nonfunctional disease suppression has existed as long as four days without uremic symptoms, whereas they almost invariably occur in organic disease within twenty-four or thirty-six hours.

DR. SOLOMON SOLIS-COHEN, Philadelphia, said that he must differ with Dr. Osborne. In a case in his early practice suppression existed for seventy-two hours without any other symptom than dilatation of the pupil. Dr. Osler confirmed the diagnosis of contracted kidney. The patient died twenty years later of pulmonary tuberculosis.

DR. WILLIAM H. PORTER, New York, spoke of the vicarious action of the kidneys and liver.

THE THERAPEUTICS OF BRIGHT'S DISEASE BASED UPON ITS ETIOLOGY.

DR. WILLIAM H. PORTER, New York: Dr. Porter draws the following conclusions: 1. All therapeutics to be successful must have for the primary object the removal of the causative factors of disease. 2. Hemorrhagic nephritis as such does not exist. It is an occasional modification of the chronic parenchymatous change. 3. Most renal lesions are non-inflammatory processes. The one exception is the exudative class. Most renal lesions are due to overwork of the glands at a time when nutrition is impaired. 4. Both the overuse and defective supply of the starches, sugars and fats are important factors in the production, maintenance and cure of renal lesions. 5. Nervous overstrain is also an important factor. 6. Treatment is to be directed both to prevent and cure. 7. It consists chiefly in the removal of causative factors. 8. It calls for a thorough knowledge of chemico-pathology

and dietetics. 9. Drugs, while not curative, may indirectly produce wonderful results. 10. These renal lesions, when studied from the histological standard only, are incurable. Considered from the physiological and chemical standpoint a large per cent are curable. 11. It is difficult to see how surgery can be made to remove the underlying factors. Hence such means cannot be classed as scientific.

INDICATIONS FOR THE RADICAL MASTOID OPERATION AND ITS RESULTS.

DR. W. SOHIER BRYANT, New York: The indications may be placed in two categories: 1. Those cases of acute mastoid involvement with extensive infection or destruction of the temporal bone, requiring the complete evacuation of all the cellular structures connected with the middle ear and mastoid. 2. Certain cases of chronic suppuration of the middle ear. The results are three: cessation of suppuration, complete lack of external deformity, and greatly improved hearing. After citing cases in illustration, Dr. Bryant concludes as follows: 1. The radical mastoid operation assures cessation of the purulent otitis. 2. It is an operation for the immediate relief of this condition. 3. It may be the operation of final recourse. 4. The hearing is much improved since in a number of cases the auditory function of the middle ear can be almost completely restored. In a small number of cases there is no improvement in hearing. 5. The cosmetic results are very satisfactory. 6. Paralysis of the facial nerve is a very rare accident in skillful hands. 7. The results are uniformly satisfactory when the best technic is employed.

DISCUSSION.

DR. T. E. SATTERTHWAITE, New York, said that in his experience the almost uniform result was that hearing was not improved.

DR. W. H. PORTER, New York, endorsed this statement. It is a question whether it is not better to proceed more slowly than to risk the total loss of hearing through operation.

DR. FREDERICK H. GERRISH, Portland, Me., spoke of sinus thrombosis in connection with disease of the ear. A radical operation is necessary to save the patient's life. He cited the case of a child twelve years old, seen two years ago. The temperature rose to 108°. He performed a radical operation, removing the clots, and the child recovered. The general practitioner should remember the possibility of this complication as a result of extension of infection.

DR. SOLOMON SOLIS-COHEN, Philadelphia: Most of the cases he had seen were in children. The patients are in much danger, and we take a great responsibility in advising delay. Hearing is a secondary matter. In a number of instances he had known meningitis, brain abscess and other serious complications to follow neglected mastoid disease. It is worse than appendicitis so far as danger is concerned. He always advises immediate consultation with a skilled aurist. He cited a case illustrating the danger of delay.

THE NONSURGICAL TREATMENT OF EXOPHTHALMIC GOITER.

DR. SOLOMON SOLIS-COHEN, Philadelphia: Dr. Solis-Cohen had recently heard a paper on the surgical treatment in which a mortality of 30% to 50% was considered a good result; 10% was considered phenomenal. He would be ashamed of a mortality of 10% from medical treatment. He related 3 cases in which he used the new serum treatment. 1. Patient almost moribund: surgeon refused even to give anesthetic. Beebe's serum given after a few days, all else having failed. Dyspnea had been a marked symptom. Ten minutes after injection the dyspnea was less and the patient was more comfortable. After a few weeks she was sent home better in every way. She remained in bed and continued serum treatment for four or five weeks, until it was no longer necessary. After a few weeks the symptoms returned, and she was as bad as before. Under the serum treatment she improved and was apparently well for two months, when another relapse occurred. At last report she was improving under treatment. 2. A drunkard. Classical symptoms present. Improved much under the serum. Relapsed and improved again, and was discharged a few days ago, the symptoms having disappeared. 3. In this case the serum gave no results good or bad after four weeks' use. In early cases it is not necessary to use the serum. Ordinarily the old treatment is efficient, rest, hygienic measures, and drugs,—ergot, picrotoxin, strophanthus, and thymus and adrenal gland. He tries adrenal first. Generally it proves efficient. It not, he gives thymus, and if necessary, both together. These failing, he goes back to ergot and picrotoxin.

DISCUSSION.

DR. PHILIP KING BROWN, San Francisco, asked why relapses are so apt to occur after the serum treatment. They are not characteristic of the disease. His results from medical treatment were about the same as Dr. Solis-Cohen's. X-rays are very efficient in reducing the size of the gland; Mayo uses them for this purpose before operating; they also reduce the pulse rate. The results from operation in his country, so far as mortality is concerned, were good. He knew of but one death, and that was caused by cutting through the gland and liberating too much secretion in the system.

DR. LOUIS KOLIPINSKI, Washington, asked whether exophthalmic goiter is strictly a surgical disease. What are the indications for operation?

DR. T. E. SATTERTHWAITE, New York, asked as to the nature of the serum.

DR. SOLIS-COHEN, in reply, described Beebe's serum. He could not answer Dr. Brown's question as to why the relapses occur. One must give the patients time to recover. The disease is of slow development and slow retrogression. Many failures are due to impatience and lack of confidence in the method employed. The indications for operation are: 1. Failure of timely diagnosis by the medical attendant. 2. Improper or inefficient medical treatment, and threatening death. With a timely diagnosis and proper medical treatment there is no need of surgical interference.

THE IMPORTANCE OF EARLY RECOGNITION OF NASAL OBSTRUCTION WITH RELATION TO DISEASE IN OTHER REGIONS.

DR. CHARLES H. KNIGHT, New York: Read by title.

THE TREATMENT OF CHRONIC VALVULAR DISEASE OF THE HEART.

DR. THOMAS E. SATTERTHWAITE, New York: The paper first deals with treatment by baths and exercises, particularly the Nauheim method. Its value is now generally recognized. The Oertel method is helpful in mild cases. The Nauheim system is adapted to a much larger class of cases, and even when a complete course of baths and exercises is contra-indicated it can generally be used to advantage. The particular muscles to be exercised, the duration of each movement, and the interval between them depend upon the views of the physician. It is well for the physician to be present at the treatment in person. The Nauheim

method does good by driving the blood into the capillaries, thus relieving the heart and lowering arterial pressure; the improved condition of the circulation promotes metabolism and nutrition; the skin becomes softer and the urine increases in quantity and specific gravity, showing that the system is more rapidly getting rid of waste products. The method is applicable to any form of heart weakness or valvular disease, whether due to loss of compensation or not, especially where there is high arterial tension, dilatation and muscular degeneration, provided the muscular relaxation has not gone too far. After discussing massage and baths, the writer turns to treatment by drugs. Strophanthus is becoming better known, and is producing better results. It acts quicker than digitalis and slower than the nitrites. Suprarenal capsule is being used more and more; it is probably the most powerful heart stimulant we have, contracting both the heart and arterioles. He has found no ill effects from as much as one fiftieth grain of nitroglycerin every five minutes in alarming cases. The dose should be increased cautiously in arteriosclerosis. Camphor acts in a few minutes and is a perfectly safe stimulant. Convallaria has had its day; it is unreliable. Sparteine has come into favor. Caffeine is a mild but rapid stimulant. Digitalis is the most effective remedy in cardiac weakness.

DISCUSSION.

Dr. F. E. Stewart, East Orange, said that the varying effects of adrenalin may in part be ascribed to the difference in strength in the preparations employed. Unquestionably some of the tinctures deteriorate on standing; this subject is being investigated in New York, and it is possible that in the future labels may be dated, indicating the age of the preparation. He had used the baths in uric acid diathesis to good advantage.

Dr. Eli H. Long, Buffalo, said that the keynote in treatment is heart nutrition. He highly commended the Schott baths. They rest the heart by lessening peripheral resistance, and thus promote metabolism and nutrition. Even when there is lack of compensation and the case is hopeless as to cure the baths rest the heart and prolong life.

Dr. Arthur H. Hall, Washington, asked how often the baths are given.

Dr. Beaumont Small, Ottawa, said that the acute and chronic forms of heart disease require different methods of treatment. The chronic forms are particularly troublesome. He asked Dr. Satterthwaite how soon after acute onset he ordered the baths. He thought it well to allow a period of rest before beginning the exercises. The chief value of the baths is in the temperature although the saline and other ingredients may have some small value. The patients are best treated at institutions, where there are adequate facilities and trained assistants. The main point is the relief of the peripheral circulation when it is congested. He commended camphor as a stimulant. The tincture is the most trustworthy of the preparations of digitalis.

Dr. Oliver T. Osborne, New Haven, agreed that institutions are the best places for these patients. The *régime* and willingness of the patients are strong factors. Digitalis is a heart tonic rather than a stimulant; it is an error to give it in acute cardiac failure, or at frequent intervals. Thus it may do harm in typhoid, pneumonia, and other acute conditions. There is much poor digitalis on the market. Strophanthus deteriorates rapidly; it should not be diluted with water. He commended nitroglycerin. Adrenalin is being a little overworked; it is not well in these cases to increase the tone of the arterioles too much. It should be remembered that the heart is only a small part of the circulatory system.

Dr. John Madison Taylor, Philadelphia, spoke of the influence which can be exerted upon the circulation through vaso-motor control by means of gymnastic exercises. The importance of these mechanical measures is often overlooked by those who deal with heart affections. There is prevalent a woeful lack of knowledge as to the vaso-motor system. He had hoped that Dr. Satterthwaite would say more as to the value of mechanical measures.

Dr. Spencer L. Dawes, Albany, added his testimony as to the value of strophanthus and its glucoside. It is almost a heresy to speak against digitalis, but there are cases with adequate compensation when it is not applicable. The preparations of adrenalin change on exposure notwithstanding the claims of manufacturers to the contrary. He emphasized the value of chloralamid as a hypnotic in heart affections. It is particularly useful in cardiac asthma.

Dr. Louis Kolipinski, Washington, inquired as to the comparative value of the Nauheim and drug treatments.

Dr. Howard Van Rensselaer, Albany, expressed the belief that the salts in the waters of the baths have no efficacy. It has been proved that salts in aqueous solution are not absorbed by the skin. Shipwrecked sailors soon become insane if they drink salt water, but if they throw over an arm or leg a cloth wet with sea water their thirst is in a measure assuaged: the water is absorbed but the salts are not. The same thing has been scientifically proved by experiments with potassium iodide and lithium. The good done by the baths is mainly due to the water pressure and temperature.

Dr. Robert Reyburn, Washington, said that his experience with the baths had been unfavorable. He had seen no therapeutic effect of long duration. What benefit there is results from friction and temperature.

Dr. Satterthwaite, in closing, agreed with Dr. Osborne that the patients can best be treated at an institution. They cannot be properly controlled at home. We must distinguish between acute and chronic heart affections. The Nauheim method is applicable only to the chronic forms. Mild cases of arteriosclerosis are suitable for treatment, but when there is danger of apoplexy the treatment is dangerous. The baths are given for ten minutes or less every other day, their number depending on whether the patient stays four or six weeks. The temperature is undoubtedly an important factor. Pulmonary gymnastics form a valuable auxiliary to treatment.

RESTORATION OF TISSUE TONUS IN THE ABDOMINAL SUPPORTS.

Dr. John Madison Taylor, Philadelphia: Between the diaphragm and pelvis the body is anatomically and physiologically weak. There is a tendency to inefficiency of the natural abdominal supports, and this tendency is accentuated by weakness of the abdominal muscles from disuse. This inefficiency is greater in some individuals than in others, and it often reaches a point where the abdominal viscera are not properly supported. When the supports are adequate there is a relatively slim waist in man and woman alike. When they are inadequate there is a dropped chest and protruding abdomen, and the lower organs are in a state of hyperemia with insufficient drainage; there is a tendency to ptosis and functional incompetence. Ordinary exercises do not reach this part of the body. The Nauheim treatment does good, but it is not sufficient. After a study of thirty years he had come to place reliance on certain exercises which are directed solely to

the strengthening of the abdominal supports. He employs artificial supports, belts, etc., until the natural supports have to some degree recovered their tone. Viscero-ptosia is a serious condition and one that is not to be remedied by the surgeon. His methods had enabled him to restore displaced viscera with marked local and systemic benefit. Time is necessary for a cure. After months, or even years, surprisingly satisfactory results can be obtained. He gave an illustration of the method employed.

A STUDY OF THE MODERN DRUG BUSINESS IN ITS RELATION TO MEDICAL PRACTICE.

DR. F. E. STEWART, East Orange: Dr. Stewart emphasizes the following points: 1. Medicine and pharmacy cannot be practiced as disassociated and independent professions as they are mutually dependent. 2. The practice of pharmacy should be carried on as a subordinate profession to medicine, and the pharmacists should be subjected to the same professional censorship as physicians by membership in societies that are in affiliation with medical societies. 3. The proper practice of the pharmacologic art requires a free materia medica and common standards, jointly established and maintained by the medical and pharmaceutical professions, and the manufacturing houses engaged in the materia medica supply business. 4. The practice of pharmacy and drug therapeutics should be limited to qualified and licensed practitioners, and the field of practice should be protected from invasion by unlicensed practitioners who set up as manufacturers and conduct their business in unfair competition. 5. Inventors of new and useful processes and apparatus for the manufacture of materia medica products, who are duly qualified by education, training and license, and who are members of regularly constituted professional societies in good standing, should be rewarded for their inventions and discoveries by patent protection.

DISCUSSION.

DR. H. C. WOOD, Philadelphia, did not believe that the science of pharmacology would be advanced by giving it over into the hands of the manufacturers. Their chemists have introduced a few useful drugs, but they are so few that the good they have done is a negligible factor compared with the harm they have wrought. The world would be better off to-day had the coal-tar drugs never been discovered. All of the useful ones can be counted on the fingers of one hand. Antipyrin has justly achieved a place in materia medica. Phenacetin is a justifiable variation. But as for acetanilid and the others, materia medica has no place for them. When we think of the number of acetanilid *habitués*, and the deaths that have resulted from its use in typhoid and other asthenic diseases we realize that the good has been much outdone by the harm.

DR. L. F. KEBLER, Washington, said that manufacturing chemists are not always given due credit for their work. He was a chemist in a manufacturing house for ten years, and he knew the sentiment without and within. His work there was as honest and sincere as that which he is now doing for the Government. Something should be done to control the sale of drugs by manufacturers directly to the public. The problem as to the matter of trademarks is working out nicely. He referred to the case of a wellknown preparation which was claimed to cure all nervous affections, including locomotor ataxia; the decision was that with such claims the preparation had no standing before the court. Finding this out, some of the manufacturers have asked the authorities how they can make their preparations creditable before the new law. This is significant as it shows that they can be kept in check, and that they are inclined to obey the law.

COMPARATIVE CLINICAL OBSERVATIONS OF THE RESULTS OF DIFFERENT IRON PREPARATIONS.

DR. ELI H. LONG, Buffalo: The comparison is between a group of the so-called peptonates of iron and the old well-known official forms. Two largely advertised preparations supposed to contain manganese in addition were chosen, and one especially prepared in the chemical department of the University of Buffalo. The official forms used were reduced iron, the tincture of the chloride and preparations of the carbonate. Fourteen tests were made upon nine patients suffering from chlorosis, or mild grades of anemia, or combined forms. The results were decidedly in favor of the official preparations, as the following summary shows: Iron peptonates used in 8 observations produced no improvement in 4 cases, very slight improvement in in 2, evident improvement in 1, and marked improvement in 1. The official forms of iron, used in 6 observations, produced no improvement in 1 case, evident improvement in 1, and marked improvement in 4. As far as these observations go they indicate that the so-called peptonates of iron are inferior to the old, well-known, simpler, official preparations.

DISCUSSION.

DR. H. C. WOOD, Philadelphia: The system requires 1-60 gr. of iron each day. With every meal we eat more iron than is necessary for the whole twenty-four hours. The iron we give as a medicine acts not as a food but as a stimulant to the blood-making organs. True organic, or food, iron has not this property, and therefore can do no good in chlorosis. The iron must enter the system in inorganic form in order to do good.

DR. OLIVER T. OSBORNE, New Haven: There are too many preparations of iron. He prefers the simpler ones and uses the tincture, reduced iron and sugar of iron. In chlorosis the trouble is chemical rather than hemopoietic; the food iron is nipped in the intestine. In anemia and chlorosis a little thyroid each day is as efficient as iron.

DR. D. OLIN LEECH, Washington, said that he preferred the tincture in small doses. He got better results from it than from the more complex preparations.

DR. BEAUMONT SMALL, Ottawa, said that he relied mainly upon the tincture, reduced iron and Blaud's pill. He believed the tincture to be the most efficient preparation.

DR. L. F. KEBLER, Washington, commended the unbiased character of the paper. Men working on a subject are apt to give undue importance to one side of the question. One should always be conservative in extolling the properties and value of drug products. Otherwise, harm may result. For instance, at the hearings of the Post-Office Department, manufacturers who have made extravagant claims for their products not infrequently claim in justification that their statements are based on the opinion expressed by some reputable physician in a paper read before some society. The claims being thus substantiated a fraud order cannot be issued. The physician thus unwittingly becomes an accomplice. He related a case in point.

DR. JAMES C. WILSON, Philadelphia, said that speaking as a clinician and not as a laboratory investigator or chemist, he believed that we cannot afford to give up entirely the use of some of the organic preparations of iron, and unfortunately most of them are of proprietary origin. Nevertheless, some of them had value, and he was obliged to give them credit. On the other

hand, he valued most highly the official preparations. He had had phenomenal success with the syrup of the iodide in diseases of children. In gonorrheal arthritis it had given him better results than any other method of treatment. He could not treat chlorosis satisfactorily without Blaud's pill.

Dr. Long, in closing, said that most of us were agreed as to the comparative value of the new advertised preparations and the old official forms of iron. In the tincture, syrup of the iodide, reduced iron and Blaud's pill, we have all that we need. The question is not as to whether the advertised preparation is efficient, but whether it is more efficient than the official forms. If not, why use it?

The following officers were elected to serve during the coming year: President, Dr. John V. Shoemaker, Philadelphia; First Vice-President, Dr. Joseph E. Janvrin, New York; Second Vice-President, Dr. Frederick H. Gerrish, Portland, Me.; Third Vice-President, Dr. Howard Van Rensselaer, Albany; Secretary, Dr. Noble P. Barnes, Washington; Treasurer, Dr. John S. McLain, Washington.

Book Reviews.

A Manual of Personal Hygiene. Proper Living upon a Physiologic Basis. By American Authors. Edited by Walter L. Pyle, A.M., M.D. Third edition, revised and enlarged. Pp. 450. Illustrated. Philadelphia and London: W. B. Saunders Co. 1907.

Our commendation of the first and second editions of this book applies to the third which is now before us. It is evident that the book has appealed to a large circle of readers, and in this last edition additions of the following subjects have been made: an illustrated system of home gymnastics, a chapter on domestic hygiene, and appendix containing the simpler methods of hydrotherapy, thermotherapy and mechanotherapy, and a section on first aid in medical and surgical accidents and emergencies. It is to be hoped that the editor will not be tempted to increase too widely the scope of a book, the attraction of which lies essentially in its brevity and clear presentation of a few practical subjects.

Text-Book on Diseases of the Heart. By Graham Steel, M.D., F.R.C.P., Lecturer on Diseases of the Heart in the University of Manchester; Senior Physician to the Manchester Royal Infirmary. With an appendix on "The Volume of Blood in Relation to Heart Disease," by J. Lorrain Smith, M.A., M.D., Professor of Pathology in the University of Manchester. Philadelphia: P. Blakiston's Son & Co. 1907.

A text-book of small size dealing with a subject so much written about is hardly expected to present much that is new. Yet Graham Steel has succeeded in treating his subject in such a way as to make a very interesting book. It differs from most of such books in that heart disease is described rather from the view point of its effect on the body as a whole than from that of a diseased single organ. Dyspnea, enlarged, tender liver and dropsy first receive attention. Even when the heart itself is considered, most attention is given to the cardiac musculature in action, not to the murmurs of diseased valves. The effect of this is to give the student a clear conception of the patient with a diseased heart and some idea as how to deal with his symptoms. To the reviewer, this seems the proper perspective through which to view cardiac disease, and will serve as a counter influence to that exerted by other text-books from which most students come, stethoscope in hand, ready to listen solely to murmurs as the important means of determining diagnosis prognosis and therapy, thereby missing entirely in very many cases any proper understanding of the case.

This book is based very largely on the author's personal experience, and thereby has that vital interest always lacking in compilations. Of course it is not possible to completely ignore the work of others, but the author rarely discusses views on which his own experience has not touched. However, in so far as authority is quoted, it is almost entirely insular — not an uncommon habit of the Englishman, which seems a fault to those living beyond the bounds of his island home.

This is a good book for the younger student because it is honest, simply told and suggestive. Its attitude toward doubtful points is expressed as follows in one chapter: "The object of the writer has been to give an account of our common knowledge of heart disease, as it has been accumulated by the daily experience of those engaged in the treatment of the disease. Beyond this knowledge there is, however, a margin of imperfect knowledge shading on the other side into absolute ignorance. It has been held that the limit of instruction to the student should be that of perfect knowledge with at most a rare trespass into the perfectly known. . . . It seems desirable to admit to the student that experience has taught that there are rare occurrences which seem to militate against our common knowledge and belief. It is better he should be warned that such exist, than that his faith in well-established clinical truths should be temporarily shattered." With this in mind, a broad conservatism is to be expected, and such is found.

The older practitioner will enjoy the pleasing style and practical suggestions of this book. While it is not profound, it contains much useful information. Though there are many points on which the reader and author may disagree, there is little that should be condemned. Most would consider the author's view as to the diagnosis of adherent pericardium far too pessimistic, and the chapter of the instrumental examination of arteries and veins is too sketchy to be readily understood. In places, undue emphasis seems to be placed on the causal relations of gout. The so-called irregular gout rests on too insecure a basis to warrant much consideration as a definite factor in the production of heart disease. Then most of what the author attributes to gout applies to cardiac disease in this country where gout is an infrequent disease. However, taken as a whole, it is a book which the reviewer takes pleasure in commending.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, NOVEMBER 14, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

THE FREQUENCY OF ANTERIOR POLIOMYELITIS.

THE frequency of acute anterior poliomyelitis is worthy of the most careful attention of the medical profession. The feeling has been growing for many years that this disease occurs in epidemic form, although its more frequent manifestation is sporadic. Various epidemics have been described in Sweden, and a very notable one at Rutland, Vt., in this country many years ago. Since then, in many places cases have occurred in sufficient numbers and so closely associated in time as to warrant the supposition that they were due to a common cause. So far as we are aware, however, the number of cases which have been observed during the past few months in New York City is quite unprecedented. It is even said that physicians are advising their patients to remain away until the epidemic which is now active shall have subsided. In our issue of Oct. 31, we printed, under the heading of Correspondence, a statement of the collective investigation of the epidemic under the auspices of the New York Neurological Society and the Section on Pediatrics of the New York Academy of Medicine. The secretary of this committee is Dr. Edwin G. Zabriskie, of 37 West 54th Street, New York, and it is altogether desirable that physicians who may be seeing these cases should report them to him with the object of determining how widespread the disease has become.

Although it seems probable that a larger number of cases have occurred in and about New York, irrespective of its greater population, it has certainly been observed by physicians in and about Boston that many more cases have occurred this year than in many preceding. Not only is this true, but apparently here, as in New York, the type of disease manifested varies widely from the ordinary text-book description of prodromal fever, followed at a short interval by a more or less extensive flaccid paralysis. Although no light has yet been shed upon the exact etiology of the affection, either through lumbar puncture or by other means of investigation, nevertheless a large amount of information, extremely valuable from the clinical and pathological standpoint, has already been gained. The most striking feature of many of the cases has been rigidity of the neck, simulating a meningitis, together with much tenderness over the peripheral nerves, simulating closely a neuritis, accompanied or followed by a more or less extensive paralysis, not infrequently irrespective of the sensory disorders. In general, therefore, it appears to be conclusively shown that the infection, whatever it may be, which has commonly been called poliomyelitis, involves various other areas of the nervous system, as well as the ventral horns of the cord. The pathological anatomy, which has been studied with renewed interest, bears out in great measure the clinical signs. A most valuable paper on the subject has recently been published (*Journal of the American Medical Association*, Oct. 26, 1907) by Harbitz and Scheel, of Christiania, on "Epidemic Acute Poliomyelitis in Norway in the Years 1903 to 1906." These writers present a masterly clinical and pathological report of the disease, the latter based on nineteen autopsies. The evidence adduced from this study is conclusive that poliomyelitis is an infection of as yet unknown etiology, that it manifests itself on the pathological side by widespread inflammatory reactions throughout the nervous system, brain, meninges and cord. Poliomyelitis is, therefore, a misnomer, except as regarded from the clinical standpoint that we are justified in calling a disease after its predominant manifestation. Admitting this widespread inflammatory reaction, it is natural that the clinical phenomena should depart in more or less measure from the accepted text-book description, and it is apparently these unusual types of the disease that we are now seeing, and which in many cases prove difficult of diagnosis for a considerable time after the onset. It is further interesting that Harbitz and Scheel, although frequently observing neuritic symptoms, found no pathological evidence of neuritis in their sections. The cause of this very striking symptom, therefore, remains obscure. The question of early diagnosis is still further obscured by the fact that the

disease frequently shows itself in adults — we ourselves have knowledge of two fatal cases within the last two months — and may very easily be mistaken for typhoid fever, as well as for meningitis or a toxic peripheral neuritis.

We beg to call our readers' attention in the first place to the prevalence of the disease, and in the second to the bizarre form in which it may manifest itself. It should no longer be regarded as one of the rarities occurring in general practice, but rather as a type of infection which certainly at this time is likely to be met in widespread distribution.

THE ART OF PROGNOSIS.

Modern medical teaching rightly has for its chief aim the development of the power of diagnosis. Students are taught not only the significance of physical signs and symptoms, but also are expected to be able to draw conclusions from examinations of the blood and various body excretions with a view to the accurate determination of the general physical conditions. That these means, given a student of ordinary intelligence, lead to the desired end is not to be questioned. However distorted the general perspective may be, we have no doubt that accurate diagnoses are much more often made by these modern means than formerly, when common sense and experience were the diagnostician's chief aids.

The question, however, arises whether this increased power of accurate diagnosis has led to a keener and more intelligent appreciation of the outcome of disease. Are our students systematically taught to observe and weigh the facts which point toward a serious or a favorable outcome with the same attention that they are instructed in determining the nature of the malady? We are inclined to think not. There is a certain excess of attention given to the causes and the development of disease, and relatively little to the means by which we may determine outcome. The problems are naturally quite unlike in their character, but we are nevertheless convinced that a course of lectures devoted to the subject of the prognosis of disease might well find a place of usefulness in the medical curriculum. It is certainly true that the chief demand made upon the physician, and particularly the consultant, is in relation to prognosis. Other matters sink into insignificance in the minds of friends and relatives. Any physician of wide experience will say that his greatest difficulty lies in determining with a fair degree of accuracy what the outcome of an illness is to be. The mistakes that are made are too numerous and apparent to demand consideration here. The nature of the question is such that mistakes are sure to continue, but it should certainly be our aim to minimize such mistakes to the last degree and to insist that students should be given the full benefit of the wide experience of their teachers in this regard. It is evident that quite other qualities than laboratory training and the capacity for ordinary observation are demanded if our prognostic ability is to stand on a par with our capacity to make an accurate diagnosis. The judicial attitude of mind needs to be developed to the fullest degree, together with a knowledge, bred of experience, of the mental and physical attributes of the patient, which no mere book study nor laboratory training is competent to provide.

MEDICAL NOTES.

Committee for Holland, International Tuberculosis Congress. — Dr. P. K. Pel, of Amsterdam, has been appointed president, and Dr. B. H. Vos, of Hellendoon, secretary of the National Committee for Holland of the forthcoming International Congress on Tuberculosis.

Tuberculosis in Pennsylvania. — Dr. Samuel G. Dixon, Commissioner of Health for Pennsylvania, is establishing a dispensary for tuberculosis in every county in the state in accordance with the law recently passed. In Philadelphia the dispensary, in charge of Dr. Alfred Stengel, will be the center from which various parts of the city may be easily reached.

A Tribute to Dr. Horatio C. Wood. — Through the interest of Dr. Horatio C. Wood, Emeritus Professor of Materia Medica, Pharmacy and General Therapeutics, at the University of Pennsylvania, a new settlement building has been given to the university. This settlement, conducted by the Christian Association of the University of Pennsylvania, has developed steadily since its inception about ten years ago. The present building has been erected at a cost of $60,000.

A Hospital for the Treatment of Diseases by Electro-Therapeutic Methods. — In gratitude to Dr. Georges Gauthier, of Paris, who recently relieved Mrs. Vanderbilt of a nervous affection from which she had long been suffering,

William K. Vanderbilt, of New York, has given the funds for the erection and equipment of a hospital in the city of Paris for the treatment of disease by electro-therapeutic methods. This building, which will be provided with all the most approved appliances in this department of medicine, is now in course of construction in the Rue Leonardo da Vinci, and the institution, it is stated, will be known as the The Foundation Vanderbilt. It is to contain 250 beds, and will be opened about the first of the year, with Dr. Gauthier at its head.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Nov. 13, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 46, scarlatina 28, typhoid fever 10, measles 25, tuberculosis 31, smallpox 0.

The death-rate of the reported deaths for the week ending Nov. 13, 1907, was 17.71.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, Nov. 9, 1907, was 205, against 219 the corresponding week of last year, showing a decrease of 14 deaths and making the death-rate for the week 17.54. Of this number 112 were males and 93 were females; 201 were white and 4 colored; 121 were born in the United States, 80 in foreign countries and 4 unknown; 46 were of American parentage, 128 of foreign parentage and 31 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 56 cases and 2 deaths; scarlatina, 41 cases and 0 deaths; typhoid fever, 9 cases and 4 deaths; measles, 14 cases and 0 deaths; tuberculosis, 35 cases and 19 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 19, whooping cough 0, heart disease 27, bronchitis 8 and marasmus 4. There were 21 deaths from violent causes. The number of children who died under one year was 39; the number under five years, 47. The number of persons who died over sixty years of age was 51. The deaths in public institutions were 62.

There were 2 cases and 1 death reported from cerebrospinal meningitis during the week.

BOSTON SCHOOL PHYSICIANS ASSOCIATION. — An organization of the Medical Inspectors of Schools has been formed under the name of the Boston School Physicians Association, with the following officers: President, Dr. H. E. Marion; Vice-Presidents, Drs. J. F. O'Brien and D. G. Eldridge; Secretary, Dr. H. J. Perry; Executive Committee, Drs. J. L. Ames, W. F. Bancroft and M. J. Cronin.

BEQUESTS BY A BOSTON POLICEMAN. — By the will of the late Stephen Clougherty, for many years a patrolman in the South Boston district, five charitable institutions become beneficiaries in the sum of $1,000 each; among these are the Carney Hospital and Free Home for Consumptives.

CENTENARIANS. — The death of Dennis Sheckrow, of Millbury, Mass., is announced at the age of one hundred and three years. He leaves twenty grandchildren and nineteen great-grandchildren.

Calvin Worth, of Concord, N. H., reputed to be the oldest man in that city, died Nov. 6 at the age of one hundred and one.

NEW YORK.

INCORPORATION OF SAGE INSTITUTE. — The Sage Institute, the object of which, it will be remembered, is medical research, and especially in diseases of advanced life, and the creation of which is due to the generosity of Mrs. Russell Sage, was duly incorporated in Albany on Nov. 1. The incorporators named are: Prof. Graham Lusk and Drs. Edward G. Janeway, Theodore C. Janeway, D. Bryson Delavan and Joseph D. Bryant, and the headquarters of the institute are to be on Blackwell's Island, where the city department of charities has provided a laboratory and other accommodations for its work.

MEETING OF SECTION OF ANTHROPOLOGY AND PSYCHOLOGY AT AMERICAN MUSEUM OF NATURAL HISTORY. — During the past week, at a meeting of the section on Anthropology and Psychology of the American Museum of Natural History, papers were read by Dr. C. Ward Crampton, on "Physiological Age," and by G. L. Meylan, on "Some Physical Characteristics of College Students." At the same institution also an illustrated lecture on "The Plasmodium of Malaria" was given by Dr. James H. Stebbins, Jr., before the New York Microscopical Society.

INCREASE IN INSANITY. — The annual report of the State Commission in Lunacy, just published, shows that there has been a steady increase in insanity since 1897, and that at the close of the year 1906 there were 26,357 insane in the

hospitals in the State of New York, or a proportion of about one to each three hundred of the population. It is stated that the highest proportions in mental disturbances are found in the small urban communities, a condition which is largely accounted for by the fact that in the large cities the rapid influx of population tends to keep the proportion down.

Bequests. — Under the will of Alexander Maitland, formerly of New York, who died recently at his home in Princeton, N. J., $110,000 is left to charitable institutions and societies. Among the beneficiaries are the Presbyterian Hospital of New York, which receives $20,000, and the Presbyterian Rest for Convalescents at White Plains, N. Y., which receives $10,000.

Death of a Veteran Patient. — After spending eighteen years in Bellevue Hospital suffering from organic disease of the heart, Edward Lennok, a native of Scotland, died in the institution on Nov. 4. As long as his illness permitted, he acted as history clerk in the hospital, but for a considerable time past he had been confined to bed. In recognition of the faithful services of Lennok, who was without means, the members of the house staff of Bellevue subscribed an amount sufficient to defray the funeral expenses, and he was buried with all due respect in St. Michael's Cemetery, Astoria.

Increase of Cancer. — In its last monthly bulletin the State Department of Health makes the following statement in regard to cancer: "The cancer problem is assuming more and more menacing proportions, there being reported 572 deaths from this cause in September, 1907, as against 526 in the same month last year and an average for five years of 456. Thus, while deaths from tuberculosis are held practically stationary, we are doing nothing to hold cancer in check as a cause of mortality."

Medical Men as Mayors. — The returns of the recent elections in New Jersey show that no less than seven medical men are elected mayors. In Paterson the successful candidate was Dr. Andrew F. McBride, formerly county physician of Passaic County, and the other cities now provided with medical mayors are Trenton, Rahway, Atlantic Highlands, Summit, Frenchtown and Washington.

Request for New York Exhibit at Tuberculosis Congress. — At the request of Dr. John S. Fulton, Secretary General of the Tuberculosis Congress to be held in Washington next year, Governor Hughes has sent letters to various State departments, suggesting that New York shall make an exhibit at the Congress. In his letter to the head of the Health Department he refers particularly to the gratifying results which have been accomplished at the Raybrook Sanitarium for incipient tuberculosis in the Adirondacks. A request was also made to President Schurman of Cornell University, to name delegates to the Congress from the veterinary and agricultural colleges.

1. The resistance of certain animals to acetonitrile is increased, of others decreased, by the feeding of thyroid substance. The resistance of the ordinary laboratory animals to morphine is diminished by the feeding of thyroid. The physiologic activity of the different thyroids as tested by morphine and acetonitrile varies directly with the percentage of iodin present. Iodin-free thyroid does seem to possess a very slight degree of activity. A similar but less

degree of activity is found in other glands, as ovaries, testes, prostate, etc. The various iodin compounds used alone altered in a similar manner the resistance of animals to morphine and acetonitrile, but the alteration no longer took place after removal of the thyroid gland. Hence it is assumed that the iodin acted only through the thyroid gland. The writer suggests that perhaps the beneficial action of the iodides in some diseases, *e. g.*, in arteriosclerosis, may be due in reality to its action on the thyroid and consequent increased thyroid secretion. He also suggests that some of the toxic symptoms of iodin are probably symptoms of thyroidism. Simple goiters, as a rule, are poor in iodin and may rapidly disappear after the administration of one of the iodin compounds. It is assumed that the iodin converts a relatively inactive iodin-poor thyreoglobulin into a more efficient compound, besides aiding in the secretion. In exophthalmic goiter the thyroid gland seems to be in a stage of hyperactivity, and iodin makes the condition worse by rendering the secretion still more active. [R. I. L.]

7. The writers describe in detail the pathological findings in a clinically typical myxedematous idiot. There were no thyroid lobes or isthmus, only two small lobulated cystic structures in the neck, which microscopically somewhat resembled thyroid tissue. At the root of the tongue a small nodule of typical thyroid tissue was found. Apparently this remnant had undertaken regeneration as actively as possible. The parathyroids were normal. The hypophysis showed general hypertrophy. The skeleton was smaller than normal, but the proportions were well preserved.

13. Marine finds iodine essential for normal thyroid activity. Glandular hyperplasia of the thyroid is a physiological reaction to a deficiency in iodine, and it is to be considered cretinoid in nature. These same changes were produced in puppies by thyroidectomy of the mother and in normal dogs' thyroids by partial removal. The iodine content of the thyroid gland varies inversely with the degree of glandular hypertrophy. Iodine or its compounds will reduce this glandular activity in dogs, and will prevent the occurrence of glandular hyperplasia in thyroids of puppies from thyroidectomized mothers and after partial removal of normal glands. The writer considers that colloid goiter is usually preceded by a stage of glandular hyperplasia, and in its uncomplicated form is the quiescent stage of the same. [R. I. L.]

SURGERY, GYNECOLOGY AND OBSTETRICS.
SEPTEMBER, 1907.

1. *SCHMAUCH, G. *The Histologic and Clinical Significance of Malignant Chorio-epithelioma.*

15. SINGLEY, J. D. *Some of the Factors that Influence Mortality in Operative Surgery.*

1. Following a careful review of the subject of malignant chorio-epithelioma, Schmauch is of the opinion that there is only a gradual difference between the simple invasion of the uterine muscles by villi and their sequelæ (adherent placenta, the common and destructive mole); between the localized chorio-epithelial growths limited to the uterus and placental region, and the villous infarcts, developed by deportation of villi; and finally between those cases in which the lungs were able to retain and master the scattered fetal cells (mostly syncytial and atypical forms), and the typical chorio-epithelioma malignum, which becomes generalized through metastases. Only the latter two types deserve the name of malignant chorio-epithelioma.

3. Morley has reviewed the literature and 11 cases of post-operative thrombophlebitis. Nothing new is added to the present knowledge of the subject.

6. Mandelbaum gives a valuable and interesting account of the pathology of new growths of the bladder. The various forms of tumor there occurring are well illustrated by photo-micrographs.

9. Professor Garrè ascribes his success in resection of the liver to the individual ligation of vessels with fine silk, and the subsequent through-and-through suture of the liver tissue with stout catgut. Approximation of the two incised surfaces of liver tissue is in his opinion the most successful way of controlling hemorrhage. It being best to press together two wounded surfaces by suture wherever possible, the resection should be done in shape of a wedge placed in approximately vertical direction to the margin of the liver. The liver needles of Kousnetzoff are of definite value. [W. C. Q.]

3. Stephenson presents the results in 30 cases of eye disease in which he had used the Calmette ophthalmo-tuberculin reaction for diagnosis. There were 6 cases of phlyctenular keratitis in children, only 2 of whom showed tuberculous lesions elsewhere. Reaction was positive in each case. Three cases of choroiditis reacted positively, although in none had a tuberculous focus been found by clinical examination. In 8 cases of interstitial keratitis 5 showed definite signs of inherited syphilis, and none of these reacted; the other 3 cases were positive to the test. Of 3 cases of episcleritis one reacted positively. One case of tubercle of the iris in a child reacted positively, and later the result was confirmed by a positive reaction to tuberculin given subcutaneously. A case of tubercle of the cornea in a girl of twelve reacted positively to the eye test, and later to tuberculin injected under the skin. In two cases of chronic irido-cyclitis he obtained the ophthalmo-reaction and also a positive tuberculin reaction. In one of these on tapping the anterior chamber of the eye and examining the fluid thus obtained, tubercle bacilli were found. The preparation can be obtained from the Pasteur Institute, Lille, France, in two forms: (1) as dry tuberculin in small glass vials to which the physician adds 10 drops of water, and (2) as a solution in hermetically sealed glass tubes, each of which contains several drops of the product ready for immediate use. The cost is not great.

8. In the Section on Tropical Diseases (British Medical Association) Simpson, Ziemann and others present papers on anti-malarial sanitation. Simpson discusses recent discoveries which have rendered this more precise and less costly. He discusses the first steps to be taken in a malarious district; the distance from dwelling houses that a protected zone is required; the different conditions which demand different modes of treatment, such as measures required in localities subject to tidal floodings, or in marshes at the foot of hills, and the anti-mosquito sanitation of dwellings. Ziemann discusses malaria prevention in uncultivated districts, particularly in regard to the proper administration of quinine. [J. B. H.]

7. Neuberg. *Contagiousness of Condylomata Acuminata (Venereal Warts).*

1. Körte has encountered eight cases of racemose arterial angioma. Trauma and vascular nevus were excluded from the etiology, although in one case it apparently developed after freezing of the ear. In the other cases it dated from early childhood or was congenital. He regards the affection as a true growth with a progressive tendency, and calling for extirpation. The process is essentially a new formation of arteries, accompanied by eccentric hypertrophy of the previous existing small arteries. He describes the technic he follows in removing the angioma after ligating the vessels. The danger of gangrene renders the operation unusually difficult on the extremities, and amputation may be necessary as the last resort. After removal of the new-formed vessels making up the main tumor, the peripherally enlarged afferent arteries subside spontaneously to normal size.

2. Gentzen has studied Sahli's desmoid test when employed with the fasting stomach. In 53 healthy persons the methylene-blue pill taken dry into the fasting stomach was dissolved and absorbed in a short time in 52 cases, in 33 instances in less than two hours. Methylene-blue in keratin capsules, which are certainly not dissolved in the stomach, was never refound in the urine in any of his numerous tests. He concludes from his experience that there must be sufficient digestive juice in the fasting stomach to dissolve the catgut string. The digestion in these cases is not the result of mechanical or psychic stimulation. If the methylene blue is detected in the urine from one to three hours after taking, it must have been absorbed in the stomach, as absorption from the intestine does not show until after a much longer interval. The healthy fasting stomach gives the desmoid reaction unusually promptly, and the test can be applied in the clinic, dispensing with the test meal. To determine whether the pathologic fasting stomach behaves in the same way will be the subject of a further research.

4. Goldberg illustrates with a dozen cases the differences between frequent micturition of nervous or psychopathic origin and the pollakiuria that follows enuresis in childhood. The former is often observed after opportunity for venereal infection, and is cured by assurance that such infection has not taken place. In other cases it is without relation to the sexual life, and ceases after regulation of the intake of fluids and exercises; he recommends also 20 drops of the extract of rhus aromatica three times a day. The pollakiuria following enuresis in childhood is much more obstinate. It is aggravated by ingestion of fluids, and is best treated with the usual measures for enuresis. Complete neurasthenic retention of urine occasionally occurs; Goldberg reports two such cases [L. G. M.]

7. *Neuhäuser, H. *Actinomycosis of the Female Genitalia.*
8. Schürmann. *Injury of Neck Destroying the Larynx.*

1. Heine states that iritis is always a serious affection, and he keeps the patient in bed, or at least in his room. Institutional treatment is always the best. He gives laxatives, and forbids all physical exertion. Moist warm dressings are preferred to cold, and occasionally cupping gives good results. Salicylates, sweat baths and dia-

phoretics are the chief methods of treatment; all stimulants are prohibited. With suspicion of syphilis mercurial enjunctions and potassium iodide should be pushed, in rheumatic iritis general measures with courses of mineral waters. In tuberculous cases, beside the general measures, tuberculin is often beneficial; the administration must be kept up for a long time and small doses used, never pushing it to a febrile reaction ($\frac{1}{1}\frac{1}{0}$ mgm. two or three times a week for several months). In mixed infections mercurial treatment may be combined with the use of tuberculin. The question of removal of injured eye to prevent a sympathetic iritis in the sound one is still open to debate.

3. Westenhoeffer reports a case of true plethora, which, he claims, is the fifth recorded case confirmed by the pathologic anatomic findings. Nothing is known concerning the etiology of this rare condition, but it certainly has no relation to the ordinary passive congestions, or to the condition known as, "full blooded," which may be induced by too rich diet or excessive drinking. Neither is the condition due to the withdrawal of the fluid elements of the blood. It is a true disease, and when once it is developed it continues on to a fatal end. The characteristic anatomic lesions are in the marrow of the long bones, as Türk had previously surmised from study of the blood in living cases, and the process is essentially the persistence of the infantile phase. The spleen, being the organ chiefly concerned in the destruction of the red cells, is invariably enlarged.

4. Veil, in reporting the results of the investigations made in the laboratory of the Strasburg Board of Health, says that he finds the detection of typhoid bacilli in the blood the surest means of diagnosis up to the third week, after that the agglutination test becomes much more reliable. He employs the method of Kayser, growing the bacilli for fourteen to twenty hours in normal ox-gall and then transferring to any of the well known differential culture media. In 210 cases he only failed four times to demonstrate typhoid or paratyphoid by blood culture or the agglutination test.

7. Neuhäuser reports from Professor Israel's clinic in Berlin a rare case of primary actinomycosis arising in the right ovary and involving the uterus and vagina. An operation was undertaken but the patient died later. The pathological findings confirmed the diagnosis.

1. Collin reviews Behring's work on bovine and human tuberculosis. In animals he was able to immunize and to cure, by means of his tulase preparations, especially the tulase lactin (a bacterial emulsion). With this substance he and others have had good success in treating localized tuberculosis in man. Another substance, antitulase, prepared by immunizing horses against the tulase lactin, is now in use. The former, after long continued use, confers an active immunity, the latter a short-lived passive immunity after the manner of diphtheria antitoxin. The author has used the above preparations in 25 cases of tuberculosis of the eye. With tulase lactin he begins with a dose of .01 mgm. and doubling the dose daily reaches 8 mgm. at the end of ten days, when there comes a pause of ten days in the treatment. If during the first ten days a general reaction is noted the treatment is stopped for twenty days. Antitulase is given in an initial dose of 100 mgm., and doubled daily till 2,000 mgm. are given. It affects mostly the local lesion, whereas the tulase lactin affects the general condition. All the author's cases cleared up under treatment, and though the period since disappearance of symptoms and signs is not yet long enough to permit of a positive judgment, he believes that we have in the tulase preparations a specific, in eye tuberculosis at least.

3. In 6 cases, clinically resembling typhoid fever in all points, Mandelbaum has isolated a bacillus in pure culture from blood and stools, which is distinct from the B. typhosus, and from the paratyphoid organisms of BRION and Kayser, and Schottmüller. He calls this new organism the bacillus metatyphi. The cultural differences are that the new bacillus has a much more intense growth on plain agar; on glycerin agar it forms constantly crystals resembling tyrosin, which are composed of a combination of calcium with an organic acid. These crystals are probably due to the action of the secretion of the bacillus on the glycerin agar; in blood agar, both the typhoid and paratyphoid organisms act on the blood pigment, causing a greenish yellow color to appear; this is never seen in cultures of the B. metatyphi. Animal inoculation shows the new bacillus to be less virulent than the typhoid, and the 6 cases did not run a severe course. The author concludes that his organism is distinct from, but closely related to, the B. typhosus.

6. *ACHERT, R. E. *The Prolonged Use of Digitalis.*
7. LOEWENTHAL. *The Action of Radium Rays on Man.*

2. Michaelis reviews Wassermann's work on the so-called syphilis serum reaction. In a series of cases, the author found the reaction positive in 75% of syphilitics and in 8% of nonsyphilitics. From a series of researches with the reaction in liver extracts, he is inclined to differ with Wassermann's conclusions, *i. e.*, that the reaction truly shows the presence of an antibody to the syphilitic toxin. So far he believes the reaction to be more or less empiric, but it has certain diagnostic value.

3. Watermann employed atoxyl in the treatment of 10 parasyphilitic cases (syphilis of the central nervous system and tabes with optic atrophy). The results were disappointing, as either no effect was produced, or else marked diminution of sight, and severe nervous or gastro-intestinal symptoms followed its use. He considers atoxyl dangerous in such conditions.

4. Sellei and Unterberg report 5 cases of gonorrheal pyelitis, in which the diagnosis was made by catheterization of the ureters; the gonococcus was found alone in one case, in the others a mixed infection was present. The gonorrheal pyelitis is always secondary to a cystitis. Most of these cases yield to rest and internal medication. In resistant cases, the authors have had surprising success by washing out the pelvis of the affected kidney with boric acid solution, silver nitrate 1–1,000, or 1% to 2% collargol.

6. In a large number of cases seen by Achert, a cumulative action of digitalis has never been noted. He believes that long continued use of digitalis is most valuable in

chronic affections of the heart muscle, while in fatty degeneration he has had little success from this procedure. The dose to be recommended over long periods is 7 to 14 drops, once or twice daily. [R. D.]

6. Rollin. *Nutritive Anemia.*
7. *Bruhns, C. *The Prognosis as to Life in Syphilis.*

1. Oppenheim describes a case of a twenty-three-year old male patient, who had a spastic paresis of the left leg, with atrophy of the quadriceps, also spasticity of the right leg, marked disturbance of sensation, and slight bladder and rectal symptoms. The diagnosis rested between, (1) caries, (2) intramedullary tumor, and (3) extramedullary tumor. After much study the latter diagnosis was made. At operation, performed by Borchardt, a diffuse extramedullary fibroma at the level of the twelfth dorsal vertebra was found and removed, with great improvement of symptoms. The authors consider that in all cases of doubt as to whether the tumor is of the cord or meninges, an exploratory laminectomy is not only advisable, but imperative.

3. Gutmann describes Mikulicz's disease as a symmetrical swelling of the lachrymal and salivary glands, often associated with general glandular enlargement, and without pathologic findings in the blood. The author reports such a case in a young man of twenty-seven, who had had a syphilitic infection three years before. Under KI and general hygiene the condition disappeared entirely. This is the first case of Mikulicz's disease in which the syphilitic origin is proved beyond a doubt.

7. After the disappearance of clinical manifestations, there is no means at present in the hands of the physician to say definitely that a syphilitic is cured. A review of life insurance tables shows that many syphilities die from a late result of their infection. Bruhns gives figures of life insurance reports, and finds that four out of five of the insured syphilitics die from sequelæ of their infection, inside of twenty years after the first appearance of the disease. How great the influence of early treatment is in these cases cannot be decided. The author suggests a properly organized research into this question, as being a very vital one. [R. D.]

Correspondence.

LETTER FROM PARIS.

[*From our Special Correspondent.*]

On Weil's New Treatment of Hemorrhage in Hemophilia, Purpura, and Allied Conditions.

Paris, Oct. 29, 1907.

Mr. Editor: During the past two years quite a series of articles by P. Emile Weil has been appearing in the French medical press on the state of the blood in hemophilia and allied conditions (the purpuras, pernicious anemia, hemorrhagic nephritis), and on a new treatment for controlling the bleeding that occurs in these cases. In my letter to-day I shall endeavor to give you a summary of these very valuable researches, as well on account of the originality of Weil's work, as of the practical interest of his therapeutic proposals. Having myself twice passed through the prolonged anxiety of a case of Werlhoff's disease in young girls, I speak feelingly on the subject, knowing how thankful I should have been on those occasions to have had such a remedy as this at my disposal.

The reason why Weil has been able to carry the study of this difficult question an appreciable degree forward is that he is the first to have ventured to get his hemophilic blood for purposes of clinical investigation by direct tapping from a large vein with a needle. Heretofore anything of that sort with this class of bleeders would not have been thought permissible; but Weil has shown not only that it can be done with entire impunity, but that it is absolutely obligatory here, as well as in the purpuric conditions, to proceed in this manner, if satisfactory results are to be expected, since experimentation on the peripheral blood by the mere pricking of a finger does not supply a sufficient quantity, nor does the blood flow in its natural manner when thus drawn.

He has had occasion to study more or less thoroughly 11 cases of hemophilia, beside a number of purpura, acute and chronic, primitive and secondary, some of pernicious anemia, and some where hemorrhage occurred in nephritis; he thinks that these last are due to a distinct altered condition of the blood, and ought to be put in a class by themselves and separated from the other nephritic patients, with whom there is no tendency to hemorrhage.

The study of the state of the blood in these 11 cases has led him to the belief that the group hemophilia must be divided into two perfectly distinct parts: one in which the disorder seems to be a family, hereditary affair, passing down from generation to generation (though it may skip one, or even two or three), and affecting the males only and leaving the females immune, at least so far as the important accidents are concerned; and another in which it appears to be a spontaneous, acquired condition, though he admits that the latter division may be only a provisory one, on account of the great difficulty experienced in many cases in obtaining precise information about antecedents; of the second class he has seen 7 cases, of the former, 4.

Incidentally he calls attention to the fact that it is not always easy to separate pure hemophilia, characterized by abundant hemorrhages occurring apart from any dyscrasic or infectious morbid condition, after traumatism, and never spontaneously, from other hemorrhagic conditions in which similar losses of blood occur spontaneously; some hemophils may have inexplicable spontaneous hemorrhages; some chronic cases of purpura may bleed on traumatism. It is consequently difficult to draw the line closely between these two categories, and cases of transition are frequent.

And just as it is impossible to separate certain forms of chronic purpura from certain cases of acquired hemophilia, so is it equally difficult to separate some chronic cases of purpura from some cases of pernicious anemia. Here again the transition cases come in: the abundant hemorrhages of purpura may produce pernicious anemia, the latter following and being induced by the former; or, a toxic or infectious cause may produce at the same time hemolysis and disordered coagulation. Hemorrhage hastens the decrease in the number of blood globules, and the pernicious anemia and purpura are simultaneous, the disorder being named according to the predominance of the symptom anemia or of the symptom hemorrhage.

We have, then, here to deal with a complicated and still imperfectly understood group of conditions, to the unravelling of which it is hoped that Weil's researches will prove an important contribution.

Having examined the blood of these patients according to his method, Weil finds that in the *spontaneous, autogenous form* its characters are as follows:

When a needle is inserted into a vein at the elbow, the flow of blood is seen to be quite different from what it is with a normal person; whereas with the latter the blood comes drop by drop, soon slows up, and the needle blocks after three or four centimeters, with the former it flows on steadily, rapidly and for so long as you desire. In some cases after withdrawing 20 cc. the flow is still as unimpeded as at the beginning.

Morphologically the blood is normal, both in number and characters of globules, aqueous tenor of serum, osmotic pressure, alkalinity, cholemimetry and fibrinogen. The trouble lies in a disorder of the process of coagulation, the clot forming too slowly, and in a special, non-compact manner.

When the process of coagulation is closely watched it is observed to assume quite a peculiar mode, which Weil has called *plasmatic coagulation;* the reds separate from the plasma and fall to the bottom, where they form a layer,

the plasma remaining above, noncoagulated. Gradually this plasma thickens, jellifies, and coagulation begins at its free surface and edges and extends downwards. The white clot thus formed immobilizes the cruor, which then also coagulates. When this has taken place normal retraction begins, first of the white clot and afterwards of the red, followed by exudation of clear, normal serum. Then a curious phenomenon occurs: little by little a certain number of red globules separate from the red clot, and, slipping out from among the meshes of fibrin, fall to the bottom; forming ultimately a layer of microscopically intact globules separated from the clot above by a sheet of yellow, nonlacquered serum. This appears to be a further anomaly of coagulation, secondary to the plasmatic coagulation, as though an undue proportion of the fibrin had been retained in the white clot.

The other remarkable feature in the blood condition is *retarded coagulation*, which, during the periods of hemorrhage, takes twenty-five minutes, instead of from three to five, and, after hemorrhage has ceased, to slower still, seventy-five minutes in one case, and forty-five in another. Blood coming from a surface-cut ultimately forms clots *in situ*, but beneath these clots it continues to ooze out and will not stop flowing.

In vitro, the addition of *small* doses of calcium chloride to the blood hastens coagulation noticeably; but *large* doses always delay coagulation.

But the addition of a little human serum to the blood puts an end to the whole trouble, both plasmatic coagulation and retarded coagulation disappearing entirely.

Now the disordered coagulation must be due either to the presence in the blood of substances preventing coagulation, or to the absence of substances that favor it. Making the opposite experiment to the above, adding a little hemophilic serum to some normal blood, no disturbance of coagulation ensues; it is consequently manifest that in this form of hemophilia the trouble is an absence or alteration of substances that favor coagulation, and probably of the coagulating ferment, fibrin-ferment or thrombosis, and that alone, since the addition of a little normal serum corrects the defect altogether.

The serum of cattle, horses and rabbits has the same effect, but is less active than human serum. An excessive amount of serum acts just like large doses of calcium chloride, preventing coagulation.

Clinically it is found that the intravenous injection, in such cases, of 15 to 20 cc. of human serum transforms the pathological condition completely, and renders it normal both in form and time. Twenty-four hours after such an injection a hemophil of this class can undergo an operation with impunity, such as tooth-extraction, or incision of skin and deeper tissues. In a few weeks, however, coagulation has again a tendency to become abnormal in time, though not in mode.

So much for the spontaneous, acquired form of hemophilia; now for the *family, hereditary form*. Here the state of the blood is quite different.

With these patients the blood does *not* flow freely through the needle inserted into the vein, in fact the needle may block after 2 or 3 cc. have passed, though not with clotting, but because the viscosity of the blood is greater than the normal.

In vitro, plasmatic coagulation takes place, but far more slowy than in the spontaneous form, on account of the viscius blood. Coagulation requires anywhere from two to nine hours. The clot that results is abnormal in appearance, and brittle; the blood does not seem to be chamically normal. Fibrinogen is certainly modified quentitatively and qualitively. Microscopically the whites are very low, three to four thousand.

Calcium chloride in small doses improves the condition, as in the spontaneous form; it accelerates coagulation though without altering its mode. Human or animal serum, however, seems here hardly to have more effect than the calcium chloride; and when the serum of such patients is added to normal blood, it interferes with coagulation. Both of these particulars are in striking opposition to what was noted in the acquired form.

Clinically, though, an intravenous injection of human or animal serum has a favorable effect; its hastens coagulation, and ultimately modifies the abnormal mode of coagulation, though the latter never disappears altogether.

These facts concerning the blood condition in the two forms of hemophilia are of great importance as regards its pathogenesis and therapeusis. They introduce into the pathology of the blood the notion of disorders caused by mere functional disturbances. Since one of them is a hereditary complaint, it follows that the absence or anomaly of secretion may be a species of malformation; there are, therefore, functional as well as anatomical malformities.

The separation of hemophilia into these two groups is not only apparent experimentally but clinically.

In the spontaneous form the accidents are less marked, less frequent, and require a more severe trauma for their production; they are, therefore, generally separated from each other by long intervals, between which the patient's health is excellent.

In the hereditary form the tableau is quite different. The troubles begin as soon as the child leaves its mother's arms, every accident no matter how slight gives rise to hemorrhage and may endanger its life, visceral bleeding occurs, and hemarthrosis appears at any blow on a joint, or even after muscular contraction. The latter symptom is very frequent, and may, if the child lives to grow up, end in ankylosis and muscular atrophy.

Two new views that Weil has introduced into this part of the question are, (1) the difference in gravity between the two forms; (2) the close relation between the severity of the symptoms and the degree of the blood disorder: the greater the retard in coagulation, the more serious the case. In the family form it is found that the younger the patient the graver the symptoms, though this may depend on the fact that the worse cases die before they get very far in their career. It is, therefore, evident that blood examination with these patients is of prognostic value as well as diagnostic.

As regards the etiology of hemophilia, some writers have endeavored to incriminate the liver, hepatic disorder being one of the factors of hemorrhage in purpura. It follows that mere analogy might warrant our ascribing a certain action in hemophilia to either functional disturbances or lesions of the liver. But it is found that neither hepatic antecedents nor cholemic stigmata are constant in either group of hemophils. Still, several of Weil's cases did show manifest liver disease, and there can be no doubt that the liver acts on the blood and alters it by other, nonapparent mechanisms.

In view of the fact that physiologists do not yet agree as to the mode of coagulation of normal blood, it is evidently not an easy matter for us to attempt to explain its abnormalities. A physical act for some, chemical for others, normal coagulation occurs through the breaking up of an albumin of the plasma fibrinogen under the influence of a leucocytary ferment, the fibrin-ferment, or thrombosis, into a globulin which remains liquid in the serum, and into concrete fibrin which is precipitated, dragging together with its meshes the figured elements of the blood to form the clot. But the process is apparently more complex than this, since the plasma contains salts of lime, which play a two-fold part in coagulation toward which they are indispensable, transforming on the one hand into thrombosis the prothrombosis or zymogen of the leucocytes, *i. e.*, acting on the ferment; and, on the other hand, forming a combination with the fibrin, which is a calcic albumin. In addition to this, recent researches have shown that in the process of coagulation the rôle of the ferment is an associated one, and that it can only act in the presence of another substance, called kinasis, which appetizes the fibrinogen which the ferment is intended to split up.

However these facts may be, in acquired hemophilia the pathological modification seems to be nothing more than an absence or alteration or the kinasis, the blood being normal both morphologically and chemically.

In the hereditary form, on the contrary, the process is a more intricate one. There appear to be present in the blood substances that oppose coagulation, since on mixing hemophilic serum with normal blood, coagulation is retarded.

Turning now to the practical side of the question, the therapeutic results obtained, Weil stated at the recent French Congress of Medicine (October, 1907) that in his 11 cases spaced over a period of two years, the injections

of serum have constantly proved successful in controlling hemorrhage. But of this more anon.

Leaving now hemophilia for the moment, and taking up its allied conditions, we find the blood disturbances in them to be analogous though not identical to those mentioned above. Looking at the various forms of purpura in particular, we there have plasmatic coagulation, delayed coagulation, a clot that does not retract, and an absence of exudation of serum. These disturbances are lessened *in vitro*, by the addition of small doses of serum, or of calcium chloride. Intravenous injection of serum is followed by amelioration, but not by disappearance of the blood disorder.

In acute purpura, primary or secondary, the injection has a manifest curative effect. In two of Weil's cases the hemorrhage was definitely checked and recovery hastened; in a third the hemorrhage decreased considerably; in a fourth the loss of blood ceased, but the patient succumbed to intoxication through hepatic insufficiency.

In two cases of chronic purpura the result was satisfactory, *quoad hemorrhage*, which was also the case with two patients with mixed forms of chronic purpura and pernicious anemia.

The general conclusion to be drawn from the above facts is that in all these different cases this means has proved to be an efficacious one, more so even than calcium chloride. Its action is not dissimilar to that of this salt. The salts of lime, which form a substratum to the ferments of coagulation, intensify the action of the thrombosis, that seems damaged or deficient in hemorrhagic conditions. The injections of fresh blood serum introduce directly into the circulation the ferments of coagulation, and very likely stimulate the system to produce others as well.

When a toxic cause is present in the blood, and continues to act, the check of hemorrhage may only be temporary; or, even though entire, the evolution of the underlying disorder may continue to a fatal termination, the injection modifying the symptoms only, not the disease.

MODUS FACIENDI.

The treatment is the same in all of these different groups, of whatever origin or form.

Any *fresh* blood serum can be used. Human serum is preferable, but that of the horse or rabbit will do also. Cattle serum should not be used, as it has been found to produce accidents: short but violent rises of temperature, with rigors, yawning, emesis, cyanosis and lumbar pain. At a pinch any fresh antitoxic serum would serve, but plain serum is best.

The technic is that of all antitoxic injections, — 20 cc. subcutaneously or intravenously.

The method is applicable either as a *preventive*, the day before a contemplated operation; once in a while, at long intervals, to anticipate symptoms of more or less regular occurrence; or as a *curative*, during the hemorrhagic stage of any of these disorders.

Its effect begins at the end of twelve to twenty-four hours, and lasts from one to three months. Its action is not only a general one, but local as well; consequently it is eminently adaptable to external lesions with these patients: a cut during shaving, tooth extraction, or epistaxis.

Weil long thought that the effect of these injections was only palliative; but he now sees that he was mistaken, and that they really modify the humoral disorder of hemophilia. In the case of a patient with the hereditary form, subject for years to serious hemorrhages every month, there has been no spontaneous recurrence of the symptom now for a year, thanks to a preventive injection once in three months. And the blood lesion has been found to decrease in proportion. But the patient still has a tendency to prolonged bleeding if exposed to any slight trauma, some time after an injection. From a serious form consequently these injections have transformed this patient's case into a mild one.

"SPECTATOR."

P. S. I wish to correct an error that appeared in my recent letter on Chantemesse's treatment of typhoid fever. The statistical figures there given, 712 cases with 27 deaths, were up to 1906, and not 1904. Later figures still reported at the recent Berlin Congress, September, 1907, 1,000 cases with 47 deaths, 4+% on a nearly seven years run of ordinary hospital cases, constitute unquestionably a very remarkable showing, in which time and numbers would appear to eliminate altogether the effect of chance or of a lucky series.

THE TREATMENT OF TYPHOID FEVER BY SPECIFIC SERA AND STATISTICAL METHODS OF RESEARCH.

BOSTON, Nov. 8, 1907.

Mr. Editor: The results obtained by Dr. Mark W. Richardson in his very interesting experiments with specific sera in the treatment of typhoid fever,[1] suggest the question how far the doctrine of chances may have affected his percentages. The groups of cases utilized by Dr. Richardson for comparison of results of treatment by the different sera, as among themselves and with "routine" treatment, would seem at first to be quite large, varying from 21 to 74 cases in each group, sufficiently so not to be seriously affected by chance, and yet the difference in the percentages obtained may have been wholly due to chance; or if the size of the groups had been larger Dr. Richardson's results might well have been more favorable to one or the other of the sera — or the reverse.

In 74 cases treated by routine treatment the deaths were 9.4%.

In 35 cases treated with serum the deaths were 5.7%.

In 74 cases treated with filtrates the deaths were 14.8%.

In 21 cases treated with residue the deaths were 9.5%.

I may here recall a series of observations which I made for the purpose of determining the effect of chance on mortality statistics of typhoid fever and the number of cases required to eliminate this effect (the paper was published in the JOURNAL, Oct. 15, 1895). About 3,000 cases treated by "routine" methods at the Boston City Hospital were taken for analysis and divided into groups of different sizes ranging from 50 to 1,500 cases each. The groups were made up of consecutive cases as they were admitted, without selection.

It was found that when these 3,000 cases were divided into groups of 50 consecutive cases the mortality varied from 24% to 2%, or 22%, and in groups of 100 from 19% to 6%, or 13%. It was not till groups of 700 cases each were taken that this difference was reduced to 3.5%.

In groups of 1,500 cases the difference was still 2.4%. The following table gives a summary of the results:

Groups of cases.	Highest per cent of deaths in each group.	Lowest per cent.	Differences per cent.
50	24	2	22
100	19	6	13
200	17.5	8.5	9
300	17.6	10.6	7
400	17	10.7	6.3
500	17.4	10.8	6.6
600	15.5	10.6	4.9
700	14.2	10.7	3.5
800	14.6	11.2	3.4
900	14.3	10.8	3.5
1,000	14.1	11.5	2.6
1,500	14.1	11.7	2.4

The bearing of these figures upon the results of treatment by specific methods as compared with "routine" methods seems to me to be obvious. Statistical comparisons can only give logical results. When the conditions are exactly the same in all the members of the series compared, excepting in that factor the effect of which is to be determined. But the conditions in different cases of typhoid fever never are the same. No two cases ever are even approximately alike. If they were *exactly* alike, two cases would be sufficient to prove results. Hence the necessity of taking a very large number of cases in *statistical* inquiries on the theory that in very large groups there will on the average be the same number of individual differences in each, and the conditions will average the same.

Very truly yours,

MORTON PRINCE, M.D.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING NOV. 9, 1907.

C. P. BAGG, surgeon. Detached from Naval Medical School, Washington, D. C., and ordered to the "Philadelphia" Dec. 7.

SOCIETY NOTICES.

NEW ENGLAND OTOLOGICAL AND LARYNGOLOGICAL SOCIETY.— The regular meeting of this society will be held at the Boston City Hospital, on Friday evening, Nov. 15, 1907, at 8 P. M. Papers: Dr. Francis P. Emerson, Diseased Conditions of Rosenmüller's Fossæ in their effect upon the Middle Ear. Discussion to be opened by Dr. Geo. A. Leland. Dr. Geo. H. Powers, Jr., report of a Case of Caries of the Middle Ear, Mastoid and Internal Ear, with Extradural Abscess, Pachymeningitis, and Destruction of the Semicircular Canals. Discussion to be opened by Dr. E. A. Crockett.

PHILIP HAMMOND, M.D.,
Secretary.

BOSTON ASSOCIATION FOR THE RELIEF AND CONTROL OF TUBERCULOSIS.— The attention of all members of the Boston Association for the Relief and Control of Tuberculosis is respectfully called to the annual meeting to be held on Tuesday, Nov. 19, at 4.30 P. M., in the Twentieth Century Club, at 3 Joy Street. The reports for the year will be received and officers for the ensuing year elected, in addition to any other business which may properly be brought forward.

MARY MORTON KEHEW,
Clerk.

RECENT DEATHS.

FRANKLIN BONNEY, M.D., M.D.S.S., of Hadley, died Nov. 9, 1907, aged eighty-eight years.

ARTHUR HARRIS COWDREY, M.D., M.M.S.S., died in Stoneham, Nov. 4, 1907, aged seventy-one years.

ROBERT DISBROW, M.D., M.M.S.S., died in Boston, Nov. 9, 1907, aged sixty-five years.

DR. ABEL HUNTINGTON, formerly of East Hampton, died at Islip, Long Island, N. Y., on Nov. 6.

DR. A. J. BROWER, a retired physician of Utica, N. Y., died at Saranac Lake, in the Adirondack Mountains, on Nov. 8, at the age of sixty-seven years. He was graduated from the medical department of the University of the City of New York in 1861.

DR. EDMOND HOWARD MARTIN, a retired Southern physician, died at the residence of his son-in-law, Dr. J. Harvie Dew, in New York, on Nov. 3, at the age of eighty-two years. Dr. Martin, who was a descendant of Chief Justice Marshall, of Virginia, was born in Beaufort district, Georgia, and practised in Savannah until after the Civil War. Later he removed to New Orleans, where he continued to practise until his retirement a few years ago. He then came to New York to make his home with his children, two of whom beside Mrs. Dew reside in that city.

DR. CAMPBELL COLWELL FITE, a retired physician, died in New York, after a long illness, on Nov. 9. He was born near Shelbyville, Tenn., on July 29, 1855, and was educated at the Dixon Academy, Shelbyville, and Cumberland University, at Lebanon, Tenn. He studied medicine with his step-father, Dr. R. F. Evans, and was graduated from the Louisville (Ky.), Medical College. In 1882, when but twenty-seven, he was elected Secretary and Executive Officer of the Tennessee State Board of Health, and while in this position he organized the bureau of vital statistics of that state. For several years he practised with much success in Nashville, and in 1885 was appointed assistant superintendent of the East Tennessee Hospital for the Insane, at Knoxville. In 1890 Dr. Fite removed to New York and went into commercial life, organizing the Malt-Diastase Company for the manufacture of malt products, but after some years, his health failing, he retired from business. During his career he was the author of numerous medical and scientific papers.

BOOKS AND PAMPHLETS RECEIVED.

Der Abstinentismus und seine Bedeutung für das Individuum und für die Gesellschaft. Von Dr. Gustav Kabrhel. München und Berlin: R. Oldenbourg. 1907.

A Text-Book of the Practice of Medicine. By James M. Anders, M.D., Ph.D., LL.D. Eighth edition, thoroughly revised. Illustrated. Philadelphia and London: W. B. Saunders Co. 1907.

A Text-Book of Pathology. With an Introductory Section on Post-Mortem Examinations and the Methods of Preserving and Examining Diseased Tissues. By Francis Delafield, M.D., LL.D., and T. Mitchell Prudden, M.D., LL.D. Eighth edition. Illustrated. New York: William Wood & Co. 1907.

Treatise on Diseases of the Skin. For the Use of Advanced Students and Practitioners. By Henry W. Stelwagon, M.D., Ph.D. Fifth edition, thoroughly revised. Illustrated. Philadelphia and London: W. B. Saunders Co. 1907.

Handbook of Cutaneous Therapeutics. By W. A. Hardaway, M.D., LL.D., and Joseph Grindon, Ph. B., M.D. Philadelphia and New York: Lea Brothers & Co. 1907.

Intestinal Perforation in Typhoid Fever; Its Diagnosis and Surgical Treatment. By J. E. Allaben, M.D. Reprint.

DELIRIUM AND DELIRIOUS STATES.

BY HENRY M. SWIFT, M.D., BOSTON,
Formerly Assistant Physician, Danvers Insane Hospital; Assistant Visiting Neurologist, Long Island Hospital, Boston.

DELIRIUM may occur under various conditions. Its causes are numerous and sometimes obscure, while its manifestations vary and are often atypical. The recognition of delirium is important because, when its presence is determined, the attention of the physician is turned toward the search for some cause, which, if found, may furnish suggestions for treatment.

If seen in the course of an acute infectious disease, as typhoid fever or pneumonia, the recognition of a delirium is attended with no difficulty, its occurrence here being so common, its manifestations usually so typical and its cause perfectly evident. When, however, it occurs under certain other conditions, when its clinical picture departs more or less from the type, and when no cause is immediately evident, then its recognition may not be so much a matter of course, unless a clear conception of its essential nature is possessed by the physician.

It is the purpose of this paper to describe the mental state seen in delirium; to illustrate this by a report of a few cases,[1] showing various modifications, and to consider briefly some of its causal factors.

In all delirious states we find disturbance of consciousness, with lessened power of attention, comprehension and memory, with resulting disorientation. Motor unrest and hallucinatory disturbance are usually present, but in varying degree, sometimes so marked as to predominate the whole picture, sometimes slight.

I shall begin with an attempt at a description of delirium in general, some of the psychology of which I take from Kraepelin.[2]

The fundamental attribute of most deliriums at least is apparently a disturbance of consciousness.

Consciousness is a term of which it is difficult to give an adequate definition. Following Kraepelin's description we may say that consciousness is that condition of mind under which external stimuli produce cerebral changes of some sort, of which the subject immediately becomes cognizant and is accustomed to regard as ideas, feelings, impulses, etc.[2] When, however, owing to some noxious influence, such as a toxemia, this faculty of mind is interfered with, consciousness becomes clouded.

This faculty of recognition of external stimuli may be completely abolished as in coma, or the interference may be only partial.

In delirium this faculty is usually not completely abolished, but here only the stronger external stimuli are heeded, while the rest tend to pass unnoticed; so that even at best the patient gets only an incomplete understanding of his surroundings and of what is taking place around him; and this because the impressions made by even such stimuli as reach him are only fleeting, no association between them and memories of previous experience being possible. Thus impressions tend to remain simply impressions and are without meaning.

Closely associated with this disturbance of consciousness are disturbances of attention and comprehension. Upon examination of the patient we find that his attention is gained only after more or less effort on the part of the examiner, or, if the disturbance is very profound, perhaps not at all. If we speak to him in a natural tone of voice, he frequently does not understand, — perhaps takes no notice. If, however, we repeat our question in a more insistent manner, the attention may perhaps be gained for a moment and a relevant answer given, the condition thus resembling a state of extreme normal fatigue, or that of a person on the verge of sleep. Yet any approach to a connected train of thought is lacking; but instead, the patient may give utterance to a string of disconnected talk which sometimes descends to unintelligible muttering, showing that associated with the diminished reaction to stimuli coming from without is an increased reaction to stimuli arising from within.

On account of these disturbances no concentration is possible, and all ability for mental work is in abeyance. This may be often brought out by asking the patient to solve an arithmetical problem. Often a simple addition like $7 + 8$, which is dependent only on past memories, may be correctly answered; whereas a slightly more complicated one like $17 + 25$, which would necessitate a certain mental effort, involving something more than memory alone, will not usually be solved.

Owing to these disturbances of attention and comprehension, whereby impressions are isolated and fleeting, there results an extreme memory disturbance, particularly for recent happenings. Thus, delirious patients have no idea as to the length of time they have been in a given place, and in fact can recall little or nothing of what has taken place since they have been ill. But in regard to events which have happened before their illness the case is somewhat different, and if the disturbances of attention do not act as a bar, many detached facts relating to the previous life history are correctly given.

Most striking is this difference in delirium tremens, in which condition sometimes a fairly complete history previous to the present illness may be obtained from the patient, in surprising contrast to his deficiency in recalling happenings from hour to hour.

Owing to the lack of correct appreciation of surroundings, disorientation — at least at the height of a delirium — is always present. Patients do not know where they are. Sometimes, indeed, after being repeatedly told, they may remember for a time the name of a place, but this remains for them only a name and is devoid of any real significance. Frequently their ideas in

[1] These were all Danvers Insane Hospital cases which Dr. C. W. Page kindly allows me to report.
[2] Kraepelin: Psychiat., 7th ed., vol. I, p. 155 and following.

regard to place may vary from time to time; thus at one time they may say they are in a hospital; at another, that they are at home or somewhere else.

In nearly all deliriums are present, at some time, motor unrest and hallucinations, which are often so pronounced as to predominate the whole picture and to throw into the background the manifestations above described; yet, perhaps, for some reasons they cannot be regarded as so essential and generally diagnostic as the characteristic combination of clouding of consciousness and associated disturbances of attention, comprehension, memory, etc.; first, because in atypical cases they may be absent, or at least present in only a slight degree; secondly, because they are found to some extent in many other psychoses.

The clouding of consciousness and associated disturbances of attention, memory, etc., are present not only in all forms of delirium and allied states, but also, in traces at least, throughout the whole course of a given delirium even at the onset and during the period immediately preceding recovery, at which extremes the more striking symptoms — motor unrest and hallucinatory disturbance — may be scarcely manifest.

I dwell on this, not on theoretical grounds, but because I believe it to be a point of practical diagnostic value.

I shall now pass on to the consideration of some of the various forms and modifications of delirium as illustrative of the descriptions given above.

FEVER DELIRIUM.

This condition is well known and requires no lengthy description. There is clouding of consciousness, which is greater or less according to the severity of the case. Disorientation soon appears. The attention can be gained but momentarily; or, as the clouding of consciousness deepens and a state of stupor is approached, not at all. The patient does not appreciate what goes on about him and friends may not be recognized. Hallucinations begin to recur in rapid succession, and lastly — and it is these which give the picture its most salient feature — are the disconnected train of talk to which the patient gives utterance and the motor unrest. The speech usually becomes indistinct and may amount to merely a series of mutterings of which the import is unintelligible.

The motor unrest varies from slight movements of the arms and fingers — carphologia, subsultus — to more considerable disturbances, in which the patient may throw off the bed clothing, and if not prevented, get up and wander about. Often these acts appear to be of the nature of reactions to hallucinations.

Fever delirium, being the best known, may be taken as the type. In some of the following descriptions of cases of delirium from other causes, we shall see how they depart in certain respects from this type, yet bear a fundamental resemblance to it. The resemblance consists in the fact that the disturbances of consciousness, attention, disorientation, etc., and usually motor unrest and hallucinations are present in all. They differ from one another in that these various manifestations are differently combined, sometimes one, sometimes another, predominating, thus giving the pictures their distinctive marks.

DELIRIUM TREMENS.

Delirium tremens, as differing from other forms of delirium, is characterized by the extraordinary vividness of the hallucinations, by extreme motor restlessness, by a general tremor approaching a sort of ataxia, and by disorientation, associated with relatively slight disturbance of consciousness.

The hallucinations are chiefly visual and recur with great frequency. Animals, such as dogs, rats, etc., are in the room; pictures are seen upon the wall, or the patient may fancy he is to be attacked in various ways.

Instead of the purposeless carphologia of the febrile delirium, the actions are rather of purposeful character, and the patient may busy himself in performing various acts, or live over again the scenes of his accustomed daily life; all this being, in large measure, a reaction to the hallucinatory episodes through which he is constantly passing. The movements are performed actively, but accompanied by the characteristic coarse tremulousness or ataxia.

Most interesting is the association of complete disorientation with relatively clear consciousness. While not knowing where he is, nor appreciating at all the nature of his surroundings, the patient is yet usually capable of answering questions in a relevant manner, and his conversation does not show that incoherence generally seen in other forms of delirium, although indeed the attention cannot be long held on one thing, being constantly distracted by the ever recurring hallucinations.

Another interesting feature, which is, however, to some extent present in all deliriums, is the disproportion between the memory disturbances for recent and remote events. Patients, while unable to recall what has happened a few minutes before, may yet be in a condition to give quite a little of their previous life histories.

The comprehension, too, is less affected than in other forms, so that patients understand more easily what is said to them, and as has been already mentioned, answer relevantly, — all this rendering a certain amount of rational conversation possible.

Allied to delirium tremens is alcoholic hallucinosis, but differing from it in that the hallucinations are chiefly auditory, and not accompanied by any considerable disturbance of consciousness or by disorientation. Between the two conditions are intergrading forms.

In alcoholic conditions the disturbance of consciousness may become deeper than in ordinary delirium tremens and the hallucinatory unrest less violent, as in the following case:

Male, forty-seven. Danvers Insane Hospital.

Onset ten days before admission, following a spree. Became confused, picked things to pieces and threw

them about. Slept at times, but at other times got out of bed and wandered around his room. Not noisy. *Never appeared to see or hear imaginary things.* History of a long continued alcoholic excess.

Examination. — Sept. 2. Lies in bed turning head from side to side. Later threw off bed clothing and tried to get up. Then sat for a while on the edge of the bed, muttering.

Apparently deep disturbance of comprehension, and does not seem to notice anything which happens about him. Hard to attract his attention, yet when questions are repeated he gives an occasional relevant reply and understands enough to obey a simple direction. When shown objects names intelligibly only "handkerchief." At no time has there been evidence of hallucinations.

Emotional tone indifferent. Untidy. Speech thick, suggesting paresis of tongue or throat muscles. Gait unsteady. Moderate tremor of tongue and hands.

Sept. 6. Weaker. More restless.

Sept. 9. Less restless. Speech largely inarticulate. Does not appear to recognize persons nor even familiar objects.

Sept. 16. Considerable improvement, both mental and physical. Speech is plainer — answers simple questions relevantly. *While he remembers he was in Danvers Insane Hospital twelve years ago, he does not realize that he is there now.*

Quiet. Habits now neat.

Sept. 22. Has become oriented for place, but not for time. Memory clear for past events, but does not know how long he has been in the hospital. Good insight. Appreciates he has been out of his head and that drink was the cause of his trouble.

A month later discharged; talk and conduct normal. Good insight. Memory hazy only for period of illness.

This case differs from ordinary delirium tremens in that the disturbances of consciousness were deeper, in that the motor unrest was less turbulent, and in that hallucinations, if present, were not demonstrable. Furthermore, the duration was longer than that of ordinary delirium tremens, the attack lasting several weeks instead of several days. Yet with the exception of hallucinations, all the characteristic disturbances of delirium were present and the diagnosis "Delirium" was justified.

In some respects the case resembled the type of the asthenic delirium seen in exhaustion conditions, and perhaps a poor physical condition may have been one causal factor, yet the psychosis occurred in a person of alcoholic habits, and the tremors and peculiar speech affection suggesting an accentuated form of the talk of a drunken man were typically alcoholic.

The following case of alcoholic delirium differs from the above in that hallucinations were prominent, in that it was associated with a polyneuritis, in that its course was much longer, and in that the outcome was not recovery but emergence into a state characterized by a peculiar memory disturbance, which is known as "Korsakoff's psychosis." The notes on this case were made by Dr. H. W. Mitchel, with whose kind permission I give a short abstract:

Male, thirty. Danvers Insane Hospital.

Alcoholic habits.

Onset gradual, four to six weeks before admission. Talked excitedly; saw bugs, also people coming and going through the window. Symptoms intermitted at times when he would appear all right, then would recur. Slept poorly. Restless.

Dec. 18. In state of hallucinatory excitement; deep clouding of consciousness; inaccessible and hard to gain his attention, being constantly distracted by hallucinations. Fights the bed clothing; struggles when attempts are made to care for him. When physicians approach, shouts, "Get away, get away," and says something about a woman being behind him. Picks imaginary insects from face and blows them off his fingers.

Occasional relevant answers, but attention could not be held, being replaced by a spontaneous flow of disconnected sentences: "The stuff is boiling out. Have you made that, Kelly? [Points to ceiling.] Raise it up again, raise it up. Put it back the way they were. I'm going to clean up the stairs. Here, wait a minute. No, don't blow my brains out. Keep the lights a-going, boys. No, that's a bluff. Here, go ahead with the machine," etc.

Physical examination showed the presence of a polyneuritis.

Dec. 19. Constantly hallucinated, picking at bed clothing. Impossible to keep attention long in conversation.

Question. What did you do last night?

Answer. Well, I couldn't tell.

Q. Where were you? [No answer, but gazes fixedly at ceiling without reply.]

Dec. 27. Condition unchanged. Difficult to gain his attention. Questions have to be repeated before getting a reply.

Q. What is this place?

A. Hospital and prison; oh, they are burning me alive out there. [Shudders and groans, then turns and gazes furtively about the room.]

Jan. 1. Inaccessible to questioning. Only spontaneous disconnected talk with pauses in which he looks about him or at ceiling. *Speech has become thick* and almost inarticulate.

Jan. 29. Improvement. Less noisy. Questions now answered relevantly, but memory defect for immediate happenings. He came here last night, a whole gang of fellows came with him. To-day he was out walking with a whole gang of fellows. Disoriented, no grasp on surroundings.

March 7. Improvement in physical condition, but still noisy, talking and shouting. Strong enough to get out of bed, but walks with a feeble steppage gait.

June 12. Quiet; disoriented; *memory disturbance* and *fabulation*. Steppage gait. Movements show considerable degree of inco-ordination.

This brief abstract shows how, as the case progressed, the clouding of consciousness, disturbance of attention and the hallucinatory unrest gradually became less while the disorientation and memory disturbance persisted, the end result being a Korsakoff's psychosis.

The following is a case of bromide delirium occurring in an attack of manic depressive insanity (recurrent mania):

Woman, twenty-four. Danvers Insane Hospital.

History of six previous maniacal attacks. At the onset of the present attack she had been given large quantities of bromide at home, in the hope of aborting the attack.

On admission — stuporous. Physical condition weak, so that she had to be carried to the ward.

After admission, usually restless, so that constant attention is required to keep her in bed, but at times sleeps a little. Tendency to throw off bed clothing

and clutch at foot of bed. If allowed to get up she wanders weakly about, but soon falls. *Speech thick;* much is unintelligible. *Drools.* Disoriented. Said at one time she was in a hospital, but different places at different times; yet recognized nurse whom she had known at earlier commitment, and finally, after being asked several times, gave physician's name correctly. Generally difficult to arouse her from her stupor and to gain her attention so that she will answer questions.

After a month, consciousness became clearer and she began to have a better understanding of her surroundings. Before this she would sometimes suddenly emerge from an apparent stupor and throw things about and knock over chairs. Then hallucinated at times and apprehensive. Told nurse that somebody was about with a dagger trying to kill her. Her physical condition improved. Later the hallucinations and apprehensiveness faded out and she gradually became exhilarated, noisy, playful and her conversation flighty, her mental condition now being like that of her previous maniacal attacks.

This case is interesting as showing a psychosis within a psychosis. At the beginning, the stuporous condition was predominant, the clouding of consciousness being deep, and the attention and comprehension correspondingly affected. From the first, the restlessness gradually became more violent as the maniacal state was approached. Hallucinations, at first not evident, later made their appearance, and then when the maniacal state became fully developed, again disappeared.

Characteristic for bromidism was the drooling and thick speech, the latter of which, however, as we have seen, is also sometimes met with in alcoholic conditions.

The next case to be described is one of senile delirium, the condition, however, being perhaps in part dependent upon chronic exhaustive physical disease; also, possibly, on alcohol.

Woman, aged sixty-six. Danvers Insane Hospital. Practically no history obtained, except that the patient had previously been alcoholic, and that the onset of the psychosis was gradual.

Examination. — Generally poor physical condition. Arteries generally thickened and tortuous. Heart sounds rather sharp. Restless. Walks feebly — would fall if not prevented. Deep disturbance of consciousness. No grasp on surroundings. Talks incoherently; occasional relevant answer, but attention cannot be held and she immediately wanders, distracted, perhaps by visual hallucination or ideas arising from within.

Q. Where are you?

A. I don't know — I don't know that at all. [Looks about her.] Oh, there, he has got my watch away now. I wish you would send my dinner over. He kept me from getting my meals. [Picks at folds of the bed clothing.]

Q. What are you looking for?

A. Something was put down at my side last night.

Q. Have you lost anything?

A. Yes, the cat — see over there [then mutters unintelligibly]. Such a place as he left me; he tore my clothes and didn't leave a stitch to put on me.

Marked impairment of comprehension. Frequently questions not heeded or answer is irrelevant. When relevant answer is given it is usually only after several repetitions of the question. Names correctly a few familiar objects; at other times cannot be made to understand what is wanted. Obeys a few simple directions, like picking up a pin, etc.

Memory. — Completely absent for present happenings, but recalls a few isolated facts from life history. Gives father's name, — father and mother are both dead; lost her eye in a mill; has been in this country thirty years.

Frequent visual hallucinations. Gets up and looks under bed as if hearing something. Looks at other patients and smiles. Peers around. Looks at walls as if seeing something there.

Considerable motor restlessness, getting out of bed, etc., apparently due to reaction to hallucinations.

A week later became quieter. Disturbance of comprehension as before, but less distracted by hallucinations which are now not so prominent.

Gradual failure and, after two months, death from terminal pneumonia.

At autopsy, performed by Dr. Southard, beside various senile changes and a lobar pneumonia was found an undiagnosed cancer of the stomach.

This case differed from a simple senile dementia in that the disturbance of consciousness was much more extreme; also in the great motor restlessness and, at times, almost constant hallucinations. In ordinary senile dementia, disorientation, lack of appreciation of surroundings, memory defect, and frequently a degree of motor unrest are present. The consciousness, however, remains relatively clear, the patient understands what is said and the attention can be held without particular difficulty, although, of course, the capacity for mental work is low.

The practical importance of the distinction is that a delirious condition as such may improve and pass into a comparatively comfortable state of quiet dementia. That this did not occur in the present case was probably due to the presence of a chronic exhaustive disease.

The following case I considered to be one of delirium dependent upon organic cardiac disease in a patient with tabes:

Woman, fifty-six. Danvers Insane Hospital.

History incomplete. Had been in bad health for several years. Treated seven months in a general hospital, where she had "several attacks of insanity." One week before admission to Danvers, very active mental disturbance, — said it was snowing and wanted windows closed to keep it out. Stared vacantly. Did not recognize anybody.

Examination. — July 4. Color pale with lemonish tinge. Heart enlarged, action weak and irregular — 112 — pulse slower than heart, systolic murmur at apex. Lungs, numerous râles at bases. Liver extends 2″ below costal margin. Urine that of passive congestion. General edema. Hgb. = 80.

Pupils stiff to light. Knee jerks absent.

Mental. — At admission somewhat stuporous. Quiet at first, later became noisy. Resistive at times. Answered a few questions relevantly, but attention soon flagged and difficult to gain it again. Seems to make no effort to think; memory very defective for recent happenings. When asked how long she had been here, said, "Twenty-six, twenty-six, twenty-six; oh, dear me, suz! twenty-six, twenty-six, no, twenty-six; that is all I know is twenty-six, twenty-six: oh, dear, I wish I knew." No definite delusions, but refused milk, saying it was poisoned; but later drank two glasses after a little coaxing.

July 26. Slight improvement. Generally quiet and not so resistive. Not oriented, but answers questions better. Tells her name, but says she is twenty years old. Rather distractible. When paper rattles or nurse whispers, she is startled. Recognizes she is in a hospital, but does not know where.

Q. Have you been out of your mind?

A. I guess I must have been.

$2 + 2 = 4$, $6 \times 9 = 54$, $29 + 36$, unable to tell. Counts correctly to ten. At times hallucinated. Heard some one say she would be murdered; a snake had crawled into her bed; saw a man come into the room with a snake.

Aug. 1. Physical condition better. Talks rationally. Appreciative of what is done for her. Realizes that she has been out of her mind. Names President and king of England; also capital of Massachusetts and of United States. Memory — 2–9–4–7 correctly recalled after thirty seconds' pause. Appreciates the gravity of her condition. Does not believe she can get well, and hopes she will have an easy death.

Aug. 11. Comfortable, oriented, no active mental disturbance except rarely a hallucination.

Sept. 1. Physically not as well. Edema has increased. Mentally clear, no hallucinatory episodes. Gives fair account of previous life history, with a few discrepancies, but does not remember what took place at the general hospital a few days before her admission here. Oriented, giving date and day of week. Slight sensory disturbance over region of breasts.

Sept. 29. Has gradually failed. Of late has shown some confusion and occasional apprehensiveness with hallucinations. Edema of legs extreme. Ascites. Bubbling râles throughout chest. Pulse irregular and feeble. Dyspnea. Death.

The diagnosis " delirium " might be questioned; some, perhaps, preferring to regard the mental symptoms, associated as they were with stiff pupils and absent knee jerks, as manifestations of a general paralysis. Yet characteristic symptoms of general paralysis, as ataxic speech, lack of insight and evidence of extreme deterioration, were absent. Instead of these we find at times a combination of symptoms which characterize a delirium, namely, disturbances of attention and comprehension, the whole picture suggesting less a dementia than mental fatigue and inability to think, which later largely disappeared. Hallucinations and motor unrest are met with also in general paralysis, but are not usually of so transitory a nature as in this case. But most out of harmony with general paralysis was the reasonableness of the general manner and conduct after the mental confusion had passed.

A study of the cortex might have been helpful, but unfortunately, autopsy was refused.

I have further, among my cases, one of an atypical delirious condition, with deep disturbance of consciousness, but without hallucinations or considerable motor unrest, beginning soon after childbirth. The condition was apparently dependent (in part, at least) upon an obscure physical disease. As this case was very obscure I will omit a detailed description.

CAUSES OF DELIRIUM.

The nature of the psychosis should be, if possible, determined by an examination of the existing mental state. If the diagnosis of delirium can thus be established, a cause should be diligently sought. It is preferable that the procedure be in this order: first, diagnosis of condition, then search for a cause. For, to assume without analysis of the present condition, that a psychosis is a delirium merely because some possible cause of delirium happens to be present in the history may be misleading, as in differently susceptible individuals similar agents do not always produce similar effects; and many psychoses occur independently of any known cause.

I shall now consider briefly some of the causes of delirium. In this enumeration, however, I lay no claim to completeness.

Most common are acute infectious diseases as in typhoid fever, pneumonia and septicemia. In these the delirium may be due in part to toxemia, in part to pyrexia. Kraepelin makes mention of such conditions as the delirium seen in influenza without high temperature and the violent, initial delirium of typhoid, as being presumably dependent upon toxemia alone. The delirium sometimes associated with chorea, he is also inclined to regard as due to an infectious agent.

Delirium may also be met with associated with disorders of metabolism as in uremia.

Of drugs which may be mentioned in addition to alcohol, are the bromides, salicylates, chloral, morphine and cocaine. A case of chloral delirium resembling delirium tremens has recently been reported by Dr. H. W. Mitchel.[3]

Next in importance are various conditions of exhaustion as factors in producing a delirium, as when it arises or continues after defervescence in acute febrile disease. Or it may arise during chronic wasting conditions, or after loss of blood. The delirious states following childbirth may be due either to exhaustion or to toxemia, or sometimes to a combination of both. When occurring in cardiac insufficiency, it might be ascribed either to exhaustion or perhaps to cerebral anemia.

Kraepelin separates the exhaustive and toxic deliriums, believing that in some cases at least the difference in symptoms is sufficient to justify distinct groupings.

In many cases the disturbance cannot be assigned to any one cause, but seems to be due rather to a combination of factors, as pyrexia and toxemia in acute febrile disease, or childbirth and exhaustive disease as in our last case. Or, as in another of our cases, to senility, alcohol and exhaustion.

Occasionally a delirium may arise for which, in spite of the most diligent search, no cause can be discovered.

DIFFERENTIAL DIAGNOSIS.

When a delirium is atypical, its diagnosis may be difficult. In general it may be said that it should be made on the presence of the characteristic mental symptoms.

From general paralysis it is to be differentiated by the absence of ataxic speech and other physical signs, and by the indication of mere abey-

[3] Chloral Delirium: A Case Report. Bost. Med. and Surg. Jour., Jan. 31, 1907.

ance of mental functions in place of actual intellectual deterioration.

In catatonic excitement or stupor, a sort of barrier seems interposed between the examiner and patient, which cannot really be broken through, while, in delirium, unless the clouding of consciousness is very deep, the patient is usually not entirely inaccessible, so that occasional relevant answers to questions may be obtained. In excitements the motor activity is coarser and of a more senseless character. When typical signs of a catatonic condition, such as stereotypy or cerea flexibilitas are present, the diagnosis is, of course, rendered easier.

In manic depressive insanity, when the excitement and flight of ideas is so extreme that a certain clouding of consciousness results, perplexities may arise.

TREATMENT.

The treatment, of course, should be directed to the cause, and when the condition is due to the ingestion of a toxic substance, as alcohol, bromides, etc., this cause may be removed.

It is to be remembered that we frequently have to do without a condition which is primarily physical and not mental, and the treatment is somewhat the same as that of any acute disease, the chief indications being to keep up the strength of the patient by appropriate nourishment and to prevent exhaustion from the motor unrest, which is frequently extreme.

Of quieting measures the continuous warm bath is generally preferable to soporific drugs. By this method — which is warmly advocated by Kraepelin — the patient is kept in a warm bath at 92° to 95° until the restlessness subsides, and is then put to bed, when he frequently falls asleep. When restlessness reappears he is again placed in the bath, and this procedure is continued until his quiet becomes permanent.

This method is particularly useful in delirium tremens; but in asthenic conditions, caution must be used, and the patient's pulse and general condition carefully watched.

In some cases soporific drugs may be combined with the bath treatment.

Heart stimulants, as alcohol, strychnia and digitalis, may be indicated. In alcohol delirium, however, alcohol should be avoided, and if polyneuritis exists, even small doses given as a stimulant may be distinctly harmful.

When a delirium tremens is threatened during enforced abstinence in the course of an acute illness in an alcoholic person, the case is somewhat different. On this point a diversity of opinion exists, but I am inclined to believe that small doses of alcohol are here beneficial.

In senile delirium, also, the effect of alcohol may be distinctly good, being not only stimulative but sedative as well.

Nourishment should be given at regular intervals as in any acute illness. If, owing to the mental condition, the patient cannot be made to take the necessary amount, tube feeding may become necessary.

PROGNOSIS.

The prognosis is in general good when no underlying, incurable cause exists. In senile conditions and in prolonged alcohol delirium, an outcome in deterioration is to be feared.

UNDERFEEDING AND ITS ASSOCIATED ILLS.*

BY DUDLEY ROBERTS, M.D., BROOKLYN, N. Y.

THE state of nutrition of an individual, a race or a nation in large part determines relative fitness and consequent natural selection. Undoubtedly the dietetic habits are of primary importance in determining this question of nutrition; an improper food supply is detrimental to health, just as abstinence from food is incompatible with life. The effect of innumerable other factors in determining the state of nutrition is very evident but of secondary importance. The best habits tend to increase efficiency under given conditions and to make for the perpetuation of their possessors. The standard customs of a people are, then, actually evolved by choice and the force of circumstances, In any discussion of the best habits of diet it is not proper to overlook these facts; if a choice is to be made between the customs of different individuals or peoples, we have strong *a priori* grounds for the belief that the best habits obtain among the most efficient and the most successful in the struggle.

Whether we turn to history or draw our facts from the lives of those about us, we notice few examples of individuals or groups of individuals showing average efficiency while living on a dietary markedly under average. Among the most efficient physically, at least, the minimum has been shunned and the most liberal food supply has been sought. There are many interesting examples of "physiological economy in nutrition" that stand out as unexplainable exceptions. History furnishes us with no examples of groups of people of such a type achieving or becoming dominant. Generalized reductions in the dietary standards of a highly efficient people, based on theoretical considerations and brief periods of experimentation, seem, therefore, open to serious question.

During the past few years, however, there has arisen a vague idea that the people of this country eat too much; although there has been nothing approaching proof to show that the majority suffer from overeating or would be in better health on a lower dietary standard, this impression has many adherents among the medical profession. Such a broad generalization is hard to attack; it savors of fighting with shadows. Certainly, derogatory statements as to our general average of health are entirely unjustified; the average efficiency suggests no general physical incapacity. There is no reason to believe that the strong would be stronger for diminishing their food supply. If rhyme or reason there be in

* Read before the New York State Medical Society, Albany, N. Y., Jan. 30, 1907.

this prevalent impression, reference is actually made to a class taking little physical exercise, living under high tension, eating improper foods at all hours, frequently with great haste, and ingesting a liberal quantity of alcoholic beverages. The medical mind, struggling with the problem that this class presents, deprecates only the quantity of food ingested, and spreads the idea that overeating is common to all classes. If all instances of poor health be studied with care, free from preconceived prejudice, I am of the opinion that we shall reach an agreement that those who suffer from the over-ingestion of suitable foods eaten in proper amounts at one time and always in a correct way, are indeed few in number.

In the general clamor on this subject the great danger of eating too little has been very generally forgotten. I am convinced that there are many conditions incident to present day life that make for this menace to health. While figures on such a subject as this are not readily given, it is my conviction that more instances of true underfeeding come to my attention than cases of actual overfeeding in the sense in which that term has been used above. The resulting discomfort, loss of efficiency and danger of intercurrent disease indicate to me that of the two evils overfeeding is the preferable one.

There are two reasons that account in large part for the fact that underfeeding is so generally overlooked. In the first place, the present tendency of medicine is toward diagnosis of abnormalities existing in each and every organ. Underfeeding induces innumerable such abnormalities, the fundamental cause of which is not considered. On the other hand, underfeeding is corrected in the prosecution of some of our most valued forms of treatment, and the true cause is unknowingly removed; such therapeutic measures as change of climate, of scene and occupation, life in the open air, exercise, improvement of psychic control, gastric lavage and many tonic medicines depend in large measure on the improvement of nutrition resulting from a more abundant food supply; rest has a similar effect in decreasing the demand for food.

Those who have seriously attempted the determination of underfeeding have encountered a difficult problem; namely, What constitutes underfeeding and how is it to be recognized? As underfeeding and overfeeding are each compatible with unusual leanness or excessive corpulency, we cannot depend on standards of weight to furnish an absolute guide. The *per diem* ingestion of food varies widely in some instances from the standard without disastrous results, and we should not endeavor to decide the question simply on the estimation of the dietetic habits. The different ills occasioned by underfeeding are often caused by conditions detrimental to digestion, or the utilization of food or by depleting processes, and we cannot consider a resulting clinical picture as more than suggestive. The only absolutely final criterion is the effect of an increased diet. I do not advance the absurd proposition that all chronic ailments are to be treated with an increased diet, but I do contend that individuals afflicted with ills known to arise from poor general nourishment, who have the physical conditions suggestive of such a state and who on careful study are found to be living on an amount of nutritive material lower than is usually taken under like conditions of physiological activity, — that such individuals are entitled to the experimental test of treatment. In this way and only in this way have we positive proof of a tentative diagnosis; we are entirely justified in withholding all other possible modes of treatment until this important question can be finally settled.

No effort looking toward a complete knowledge of the gastro-intestinal tract and all its functions is to be spared; every possible cause of excessive waste of energy or destruction of tissue demands a careful search. Fortunately, our methods of accurate observation are constantly being increased. It is clearly appreciated that the removal of all these conditions is of primordial importance; when, however, this is impossible, it is clearly evident that we must supply food in such quantities that the general nutrition is built up in spite of abnormal waste. This is now the accepted practice in tubercular conditions. Failing in our search for a cause of excessive waste, we must turn to an actual failure of intake of nutritive material.

The clinical determination of the amount of true food stuffs habitually ingested by our patients has not been on a practicable basis, and consequently has infrequently been made with any degree of accuracy. We have absolutely no guide in the offhand answers of patients. The weighing of food is impracticable for general use. I have found that the caloric value and nitrogen content of certain bulks of food as eaten may be accurately determined if the patient under cross-examination can state his usual habits for each meal, using simple units of bulk as measures of quantity. Occasionally it is necessary to have records kept for several days. The nutrients and albumin contained in certain bulks of the commoner foods are given in tables published by the writer[1] or can be estimated by the more elaborate method of Fischer.

Daily observation of the diet of different classes of people has convinced me that with the gradual diminution of muscular labor there has been a natural tendency to lessen the food intake; in consequence of this our food standards to-day are, on the average, somewhat lower than those compiled by Voit, Atwater and others of an earlier period.

From an analysis of cases occurring in hospital, clinic and private practice it would seem that there are three chief causes of habitual underfeeding,— the effort to save time and money, the loss of appetite and complaints referred to the stomach. One or more of these three causes can almost always be found, and each tends to become more operative as the struggle becomes keener. Inherited customs might be spoken of as playing

[1] Jour. Amer. Med. Asso., April 21, 1906.

a predisposing part. The curtailment or omission of meals is exceedingly common because of the great demands of commercial and school life. Experience teaches that less discomfort results if meals are curtailed than if bolted, but underfeeding may gradually ensue. The cost of food is relatively high in our larger cities and among the poorer classes economy is practised to a dangerous degree. Loss of appetite is dependent on many conditions of mind and body; indoor life, physical and mental fatigue and emotional states are particularly common causes. The appetite may be described as "ravenous," but a few mouthfuls of food cause satiation. Loss of appetite is a condition incident to prolonged undernourishment, and the individual who for any reason eats too little food generally loses the natural desire.

In a very large proportion of cases underfeeding is due to attempts to relieve true or fancied gastro-intestinal derangements. The complaints commonly held to augur digestive disorder are many and varied. Relief of digestive embarrassment is apt to follow the lessening of the demands on the stomach, and if this diminution of food be temporary or carried only to a point of safety it is a valuable mode of treatment for many conditions. When spontaneous or induced recovery does not come about, the sparing of the stomach continues, and to the real or imagined trouble is added undernourishment of the entire body and actual gastric weakness. The physician is often responsible for this underfeeding, in failing to see that sufficient food is taken to keep up the nourishment. We have been careless of the fact that dietetic prohibitions are dangerous in the hands of those willing to follow them. The uncured chronic sufferer is apt to collect the advice of many physicians and try to cure himself by avoiding rich foods, starchy foods, fatty foods, sweet foods and meats.

The *clinical picture* of underfeeding is necessarily that of the various functional conditions to which it gives rise. The part of the body most affected by the general undernourishment depends on the constitution of the individual mind and body and on the work each part is called upon to perform. The nervous system is most commonly affected, as would be expected from its highly organized character; this is shown by deficiency or aberrancy of innervation, or by some irritability of weakness. Clinically there are certain types of ills most commonly seen to be due to underfeeding, and their separate study is warranted.

GASTRIC TYPES.

Functional disorders undoubtedly constitute the vast majority of all gastric abnormalities; such disorders are incident to almost every disturbance of health, but normal function returns on the resumption of proper conditions. There are, however, certain disturbing factors which tend to persist unless removed in the course of time by chance or conscious effort; in this manner a large proportion of "chronic dyspepsias" are to be accounted for. That all the various abnormalities of gastric function may result from poor general nourishment has frequently been suggested. That such abnormalities very frequently arise from habitual underfeeding is not at all appreciated, but can readily be proven by the criteria we have suggested. This has been the entire cause of such a large number of cases coming directly under my observation, cases of months' or years' duration, cases that had previously been subjected to all other plans of treatment, that I feel it is impossible for me to exaggerate its importance. Hyperacidity, subacidity, anacidity, myasthenia, atonic dilation, peristaltic unrest and spasm of the orifices, each with its particular clinical picture, may be caused simply by the ingestion of too little food. Subjectively there are complaints of belching, slight or excessive, of bloating after meals, constant or late afternoon nausea, nervous vomiting or regurgitation, loss of appetite or anorexia, epigastric pain or discomfort soon after taking food. Usually the patients are of a nervous type; generally they are rather thin, but sometimes pale and fat. Enteroptosis is common, but not always present. We are all familiar with the old and new lines of treatment to stimulate or depress the activity of the stomach. If we are interested in the study of actual causes we must probe into the dietetic habits not so much in search of objectionable foods as to see if a sufficient amount of food has been eaten. We surely cannot expect to find normal stomach functions in an undernourished individual, and yet the average dyspeptic continues to eat too little while all measures are tried except the rational cure.

We must admit, however, that having determined what we should judge to be an insufficient dietary, we are confronted with a rather anomalous situation, for the increased diet must be given to an individual who attributes many of his complaints to the ingestion of even a small amount of food. In practice it is seen that this difficulty is more imagined than real, as the patient soon discovers that two or three times the amount of properly selected food can be taken without causing more trouble. In the course of a few weeks the stomach begins to function normally and irritability disappears. The weight and general condition show steady improvement. Failure to achieve the desired result, if proper amounts of food are actually taken, shows us that we are indeed dealing with a condition other than underfeeding.

Organic changes in the stomach or neighboring organs generally tend to result in underfeeding and its associated disturbances of function, but the cure or amelioration of the organic disease is necessarily the first consideration. It should be recognized, however, that the resumption of proper dietetic habits is not necessarily spontaneous and that the persistence of underfeeding is a good and sufficient reason for the continuance of digestive disturbances following actually successful medical or surgical plans of treatment.

INTESTINAL TYPES.

The various intestinal neuroses, nervous diarrhea, mucous colic and atonic and spastic constipation are frequently found to be due to the ingestion of insufficient nourishment. This is the one dietetic plan that is rarely suggested for these conditions, but is most often of value, as it removes the causative condition while other plans depend on blandness to quiet or irritation to stimulate peristaltic activity. The patient is apt to learn, after months of suffering, that a choice of food makes comparatively little difference in these neuroses, and admits complete discouragement. If the condition is due to underfeeding, the ingesting of a generous diet and one chosen with comparatively little regard to stimulation or sedation of peristaltic activity soon shows remarkable results.

Chronic catarrhal conditions of the bowel are frequently complicated by functional disturbances from underfeeding, and the apparent failure in the treatment of some cases of colitis may be attributed to the oversight of this complication.

ANEMIC TYPE.

Although we have long known how little iron was needed by the body and how small were the daily losses compared with the iron content of almost any diet capable of sustaining life, we have continued to administer iron to the individual with hemoglobin below the average, and have constantly been on the alert to find a more efficacious form of this element. We have no reason to suppose that the red cells have the first call on the ingested proteid for use in the making of hemoglobin. A deficiency of available proteid means deficiency of hemoglobin, whether the deficiency be due to failure of proper intake or to the abnormal destruction of the ingested proteids. I am convinced that we should have these two possibilities in mind in every case of simple anemia. In the absence of those pathological conditions known to affect dissipation of energy or tissue destruction we may find, then, either a diet deficient in total nutrients but abundantly rich in proteid which is used up as a fuel food, or a diet markedly poor in proteids although little below the standard in total nutrients.

Among young children, school girls and young women there is a large number who owe their anemia to this kind of underfeeding. Some have an aversion to all albuminous foods and are overfond of fruit and candy. Others have no particular aversions, but eat little of anything. The resulting anemia is not evidenced alone by the color or estimation of hemoglobin, but often leads to attacks of faintness, dyspnea on exertion, palpitation of the heart, anemic hemorrhages and other symptoms of the true anemic state. Many of these cases have no nervous symptoms or actual gastro-intestinal disturbances. The condition of anemia has usually been recognized by all their medical advisers and iron in all its various forms administered for months. The reply to absolute and strict regulation of the diet is very rapid, if underfeeding is the true cause of the anemia. In every case of simple anemia without discoverable organic cause, this is the rational line of therapy.

NERVOUS TYPES.

The management of the class of conditions spoken of as the neuroses presents the most difficult of medical problems. Their complete understanding requires more knowledge than we possess of the psychic functions and their relation with the physical body. We are almost necessarily led into the maze of metaphysical speculation. Fundamental differences of opinion seem unavoidable. Formerly all treatment was physical, while to-day the pendulum is swinging in the other direction. It seems impossible to deny the mutual interdependence of the mind and the body. It is only in rare instances that we fail to see subversion of the higher mental faculties in depleted physical conditions. Practically it is observed that the so-called neuroses and poor general nourishment usually go hand in hand. Many have called attention to the almost universal habit among this class of individuals of eating less food than their stronger neighbors. Emphasis has usually been laid on the necessity of rest and "overfeeding" when the condition of neurasthenia or nervous exhaustion is reached. No doubt this type is more in need of radical treatment, but all about us are numbers of poor forlorn individuals living in a state of semi-invalidism, possibly able to work, but continually afflicted with "nerves"; with easily developed mental and physical fatigue, headaches and backaches, vertigo and nausea, insomnia and depression of spirits, all manner of aches and pains and disturbances of function. Some owe their condition purely to mental habits, but experience soon teaches that a stronger mind and a less irritable nervous system naturally follows an improvement in nutrition. In an astonishing number of instances a restoration to usefulness and health follows the ingestion of proper foods. The institution of the proper habits is the difficult problem to be worked out in each individual case; the tact and resourcefulness of the therapeutist are taxed to the uttermost. Harmful autosuggestions must be combated by reason and by encouraging suggestions. It is in this direction that our work as practitioners is broadening out. We are learning to treat not the body, but the whole man.

IMMUNITY AND THERAPEUTIC ACTION.

BY THOMAS J. MAYS, A.M., M.D., PHILADELPHIA, PA.

BELIEF in the existence of a principle that protects the animal organism against disease and injurious influences is coeval with the history of medicine. The *vis medicatrix naturæ* of Hippocrates, the *archæus* of Paracelsus, and the *vital spirit* of van Helmont, were but various expressions of this faith. The fact that typhoid fever, smallpox, yellow fever and many other diseases

protect against second attacks is a practical verification of this principle. The use of tobacco is another example of this. The novitiate becomes intoxicated and violently nauseated when he first begins to smoke or chew, which in the course of a short time passes off, never to reappear so long as the habit is maintained. A similar immunity to injurious influences prevails throughout the vegetable kingdom.

In what does this immunity consist, and what is its possible explanation? If one answer stands out more clearly than another, it is that it is not a guarding "spirit," or an "entity," which is separate from, and independent of, the normal physiologic processes of the body, as was believed in former days; but that it constitutes an integral and essential part of living matter. Spencer has defined life, proximately, as an organism which maintains its moving equilibrium by forces acting from within and from without; and in keeping with this definition, let us make a crude comparison between this moving mass and a spinning top. A top continues its moving equilibrium until it is overcome by the antagonistic action of external incidental forces. Now an antagonistic incidental force brings about one of two results. It either overthrows the top and brings its moving equilibrium to a premature end, or it interferes with it to such a degree that it will have to readjust itself to a new and an altered moving equilibrium. The same holds true of living matter. The unfriendly forces that disturb but do not destroy its moving equilibrium end their effects in establishing an altered equilibrium which still belongs to the confines of health. The toxic effects of tobacco, for example, establish a constitutional condition different from that which obtained before this agent was taken, bring about a readjustment of the bodily forces, and produce a toleration for quantities of this drug, which in the beginning provoked such disastrous results. Nor is there striking evidence that, if used in moderation, it produces any perceptible harmful action in the great majority of those who indulge in it. Seasickness, a disorder of the nervous system with a well recognized pathology, caused by the mechanical motion of ocean vessels, is another instance in which readjustment of bodily conditions conform to the action of hurtful external influences. Very few people who go on long sea voyages are entirely exempt from this disease, yet a single pronounced attack will give them immunity from it so long as they follow the sea. Both tobacco poisoning and seasickness are examples, then, in which bodily conditions have been forced to rearrange themselves into other but also normal attitudes, by the influences of unfriendly external forces, and there is no doubt that these results represent a broad general physiologic truth which underlies many other similar phenomena, like those of smallpox, yellow fever, typhoid fever, measles, scarlatina, etc.

What, then, is the nature of this immunity? What is its mechanism, and where is its location? Great efforts have been made in recent years to show that it consists of a process known as phagocytosis — a process in which the leucocytes of the body are supposed to be engaged principally in the special work of attacking and of devouring pathogenic organisms, and which is designated as a warfare against disease. That phagocytosis exists in the body is true, but whether its physiologic function consists in waging special war against disease is a different thing. Its element is a leucocyte in activity, possessing the characteristics of other unicellular organisms, *viz.*, of enveloping fragments of blood cells, of muscular and elastic fibers, of fat and pigmentary cells, of dust, bacteria and other foreign bodies, and of disintegrating them.

Viewed from any standpoint that it may be, there is no doubt that the function of phagocytosis is that which is exercised by leucocytes everywhere, and plays a very important part in the nutritive processes of the body, but the effort to compel it to assume the special and unnatural province of a disease-destroyer is, notwithstanding its present notoriety, too nebulous to require serious reflection. One of the highest authorities on pathology in Germany states that to define this process, the function of which is to absorb nutritive material, as a warfare against the causes of diseases, does not even rise to the dignity of a poetic conception of this phenomenon.[1]

It seems to the writer that by far the more feasible explanation of the genesis of immunity rests on purely physical principles. When two forces of unequal strength come in contact with one another, the stronger causes the weaker to move in a direction parallel to its own, and to a point where a mutual balance takes place; and although the latter may tend to rebound and to assume its former position, yet through the continuous operation of a series of such impacts, it will finally be forced to seek a new or another state of equilibrium, in which it will remain after the attacking force has ceased to act.

When a violent storm descends on a forest, each tree, individually and collectively, is forced to bear the brunt of the battle. The more unprotected, the older and feebler, trees and the weaker and more exposed branches of the younger and stronger trees, will be the first to go down in the onslaught. Even the strongest will be put to the severest test, and only those remain which possess the reserve power to fully react against the storm's fury. Every individual surviving tree is necessarily forced into another and a stronger equilibrium; and collectively, owing to the strain and furious ordeal to which it was subjected, and to the weeding out of many of its encumbering elements, the forest is physically stronger, less vulnerable, and far more able to withstand and resist a second attack of the same kind, than it was before. In other words, the forest is immune to another similar assault, and will remain so

[1] "Ein Vorgang (phagocytosis), der die Aufnahme von Nahrungsmaterial bezweckt, als einen Kampf zu bezeichnen, ist nicht einmal für eine poetische Betrachtungsweise dieser Lebenserscheinung zulässig." Ziegler, article, Entzündung, Eulenburg's Real-Encyclopædie, vol. vii, p. 88.

until time and circumstance undermine its stability.

The reaction between bodily tissues and the impact of external or internal incidental forces is, in effect, the same as that which takes place between the forest and the storm. Thus the effects of a slight blow are readily overcome; but the shock of severe injury is often grave enough to disturb the bodily equilibrium to such a degree that reaction is impossible, and death is the consequence. A strong and healthy body is much less liable to contract disease than one which is already partly broken down. Mortification and gangrene are more prone to follow wounds and injuries in individuals with depraved health, than under opposite and more favorable conditions. Wounds heal more rapidly and kindly in strong than in weak bodies. The same conflict between health and disease is witnessed in chronic ulcers, where the line between health and disease advances and recedes, causing the ulcer to appear large at one time and small at another, in direct correspondence with the strength and weakness of the part, and it is a noted fact that the line of treatment which is pursued universally is that of endeavoring to maintain the local and general resistance of the body. In threatened invasion of mortification, or of gangrene, the early application of stimulating poultices will sometimes avert the danger, or at least tend to circumscribe the process, and limit it to a smaller area than if left to its unrestricted course.

The *vis medicatrix naturæ* is, therefore, in all probability, an innate protective property of all tissues — a part of their very physiologic constitution, and does not reside in any separate special mythical or supposed real entity. Perhaps the most exact demonstration of the truth that this power of organic reaction or resistance is located, at least in the muscular tissue, and that it may be enhanced by or interfered with by drug-action, is found in the following graphic record given by the isolated frog's heart, under the influence of blood, curare and chloroform. Thus it has been discovered that curare 1: 80,000, *i. e.*, one part of curare to eighty thousand parts of 2% solution of blood, will produce the first series of tracings given in the illustration below. These tracings are slightly higher than those which blood alone is able to produce, as has been repeatedly proven. If, immediately after the curare tracings have been obtained, the heart is subjected to chloroform, 1: 500, *i. e.*, one part of chloroform to five hundred parts of 2% blood-solution, the second series of tracings is produced. Now, if after this a 2% solution of blood containing the same proportion of curare and chloroform, *i. e.*, one part of curare to eighty thousand, and one part of chloroform to five hundred parts of 2% blood-solution, is transfused through the heart, the third series of tracings is obtained.

What is the interpretation of these phenomena? First, the tracings which the heart is able to give with blood alone (not shown in the illustration), and which are slightly lower than those given by curare, in the proportion of 1: 80,000, must be taken as a standard of the normal strength or resistance of the heart muscle. Second, the tracings which are given by curare, 1: 80,000, demonstrate that this dose of curare is capable of increasing the heart's strength or resistance over and above the point which blood is capable of giving alone. Third, chloroform, 1: 500, depresses or almost entirely overcomes the heart's resistance or reaction, which is shown in the diminutive and depressed tracings; and, fourth, it is demonstrated that by combining curare in the proportion of 1: 80,000, with chloroform 1: 500 — the same doses which separately produced the first and second series of tracings — the curare dose will reinforce the physiologic resistance or reaction of the heart muscle to such a degree that it is enabled to successfully antagonize and almost wholly throw off the disintegrating effects of the chloroform dose, as is witnessed in the third series of tracings, which are nearly as high as the first series. In other words, the conflict between the two drugs is not a chemical, but a physical one, in which the heart muscle is simply the medium through which the stimulating influence of curare and the depressing effects of chloroform are enabled to display their antagonistic powers when properly adjusted.

That which is true of the antagonism between curare and chloroform is also found to be true of that of the following named drugs:

Several things are made very clear by the preceding considerations. One is, that drugs expend their forces directly on the bodily textures, and not on any hypothetical intervening medium. Another is, that small or minimum doses enhance bodily resistance, and that large or maximum doses depress or paralyze the same. And still another is, that minimum doses successfully antagonize the disintegrating effects of maximum doses. These antagonistic effects are displayed here as decidedly as if they had been wrought by the two mechanical forces of attraction and repulsion, and they give us an exact mathematical demonstration of the power which drugs have of supporting and preserving life when attacked by adverse forces. Now, if we recognize the fact that disease is but the manifestation of forces which move in a direction adversely to health, and substitute these for the operation of the maximum drug doses in the above illustrations, do we not have a clear picture before us, as to how a large class of drugs in minimum doses combat disease, *viz.*, by stimulation? On the other hand, is it not equally clear how maximum doses possess the property of depressing hyperactivity of the bodily textures — a pathologic condition which lies at the bottom of many important diseases — and thus give us at least a fundamental idea of the action of two other large classes of drugs, *viz.*, antiseptics and antipyretics?

DIAGNOSIS AND TREATMENT OF DIPHTHERIA IN YOUNG CHILDREN.*

BY F. P. WEBSTER, M.D.,
Instructor in Diseases of Children, Medical School of Maine, Bowdoin College, Portland, Me.

THIS paper is not intended to be a complete consideration of the diagnosis and treatment of diphtheria in young children. It deals with diagnosis particularly in young children, because it is among them that most cases occur, and more especially because the younger the child, the higher the mortality and the greater the urgency of diagnosis and treatment. Moreover, since the general use of antitoxin, the mortality in the very young has not been reduced proportionately to that in older patients.

In making a diagnosis of diphtheria, we have two methods: the bacteriological and the clinical.

The bacteriological method is subdivided into immediate examination of smears and late examination of cultures.

Diagnosis by smears is unreliable, as when smears show no bacilli, bacilli may be shown by culture. By a smear you can only note the presence or absence of bacilli, like the Klebs-Löffler. However, this direct method is suggestive or corroborative when positive, but when negative should be disregarded entirely.

The examination of cultures is the most certain method we have of diagnosticating diphtheria. But is this as valuable a method for purposes of treatment as the clinical diagnosis?

In recent years laboratory diagnosis has properly acquired a high position in the minds of most physicians, but I believe, in the estimation of of many, its position is too exalted. I have had sufficient experience in the midst of laboratory diagnosis to know that it has some fallacies. Aside from the possibility of error, bacteriological diagnosis must use up valuable time; in the case of diphtheria, probably, twelve hours or more. Can we afford this time for purposes of treatment?

Clinically, by certain symptoms and signs familiar to us, we can usually recognize a probable case of diphtheria. There is quite a possibility of mistake; still, bacteriological examinations have generally shown earlier clinical diagnoses to have been correct.

I believe that textbooks in their discussion of diphtheria mislead. They follow the old rule of etiology, pathology, symptomatology, diagnosis, prognosis and treatment, particularly, treatment follows diagnosis. For diagnosis they teach you to rely upon cultures. Here, it seems to me, is a disease in which, especially in young children, treatment should come first upon suspicion. Then positive diagnosis should follow for purposes of quarantine. In the hands of the general practitioner, the reliance upon culture examinations has a damaging effect upon treatment. A physician may be reluctant to make a diagnosis of diphtheria. He may feel that he is working in the interest of his patient, or the family of the patient, to avoid quarantine if possible; to wait for the report of the culture, hoping that it may be negative. He feels justified in such delay because he follows the instruction of the books. He knows that laboratory diagnosis is the surer diagnosis. He knows that his two best diagnostic aids are, first, the report of the culture; second, the spread of the membrane.

In medicine it is good to feel certain; perhaps in a dozen hours one can read, "Diphtheria bacilli found," or can note the visible spread of membrane, although the invisible spread of toxins has been vaster. One then has diagnostic security; the child has less chance of recovery. I believe that the proportionately high mortality of diphtheria in young children is due in part to reluctance to call certain suspicious cases diphtheria and to institute quarantine. An older patient can naturally better tolerate such delay.

We, as practitioners, want the earliest possible diagnosis, because the cases treated earliest have given much the best results. Then, too, isolation and immunization are more certainly accomplished.

Diphtheria antitoxin has been shown to be

* Read to the Portland Medical Club, June 6, 1907.

harmless, and may be beneficial to patients without diphtheria, *e. g.*, in tonsillitis and in scarlet fever. We shall then do no harm in giving antitoxin to a child without diphtheria. It must appear to us that lives have been lost by waiting for more diagnostic evidence, and that lives have not been lost through giving antitoxin on suspicion. If so, for purposes of treatment, which implies prompt treatment, the clinical diagnosis must be the best. Its only possible faults are that we may unnecessarily disturb families and deprive them temporarily of their freedom. Such failings seem trivial when contrasted with the fact that we must otherwise sacrifice lives.

I shall depart from this debate to mention a few cases and a few facts which I think of relevant interest. Pediatrists call attention to the great importance of the examination of the throats of all sick children. Failure in this I know has harmed patients and physicians.

I recall a case of a two-weeks-old baby whose only symptom noticed by its mother was that it would not nurse. Much to my surprise its throat showed advanced diphtheria.

In cases of doubtful diagnosis repeated throat examinations should be made. Young children, sick with diphtheria, may show no evidence of membrane formation for several days. Last winter I watched a fifteen-months-old baby for several days unable to make a diagnosis. The only symptoms were moderate fever, apathy, anorexia and occasional vomiting. The physical examination was negative until on the third day a membranous exudate appeared upon one tonsil and proved to be diphtheritic.

That very young children rarely have follicular tonsillitis should be borne in mind. Recently I noticed the statement of a German physician, Seibert, that in very young children, a probable diagnosis of diphtheria should be made upon slight evidence. It brought into my memory a patient I saw a year ago, a child two and one-half years old, sick about twelve hours with moderate fever and lassitude. On examination one tonsil showed two small patches no larger than those ordinarily seen in follicular tonsillitis, but the unilateral position and especially the age of the patient made me suspicious enough to give 3,000 units of antitoxin. The patches had nearly disappeared the next day, by the time I had found bacilli in a culture. I have seen several similar cases, which makes me believe that they are not uncommon.

My conclusions in diagnosis are that in young children, a probable diagnosis of diphtheria should be made upon comparatively slight evidence; that the dangers of waiting are so great that a clinical diagnosis is of first importance and all sufficient for the purpose of treatment; and that cultures are of value mostly for purposes of immunization and quarantine.

In larger cities where the mortality of diphtheria was from 35% to 50% without antitoxin, it is now less than 10%. Cases treated the first day show a very low death-rate, *e. g.*, in the Boston City Hospital, 180 doctors and nurses had diphtheria without a fatal result. In young children the urgency of early treatment is naturally greater. It is a fact that in early life the mortality of diphtheria with antitoxin has not been proportionately diminished. Under two years of age the mortality is still about 30% in recognized cases.

This higher death-rate in early life is attributed to a greater susceptibility to the toxins and to the greater frequency of pulmonary complications.

It seems to me that diphtheria in an infant should be entirely amenable to a specific treatment that is given early enough. I believe the higher mortality is at least in part due to such reasons as failure in the routine examination of throats, the reliance upon cultures, *i. e.*, the failure to make a diagnosis without delay, and the use of too small doses of antitoxin.

The kind of antitoxin employed is of importance, and I believe that only the newer concentrated forms of antitoxin, of which Lederle's is a type, should be used. Concentrated antitoxin is much more easily injected, — a fact of great value in treating children. It encourages the use of larger doses, and the untoward effects of the horse-serum are less.

I do not intend to go into detail of dosage, but will mention my opinion, that in young children the initial dose should average 3,000 to 4,000 units rather than less, because recovery is quicker and it is less often necessary to repeat the injection, and because, appreciating the harmless character of antitoxin, it is better to give too large rather than an insufficient dose.

In a general way it may be stated that the dose of antitoxin is not dependent upon age, but upon the apparent severity of the disease and its duration when discovered.

One should remember that a nursing mother, sick with diphtheria, excretes antitoxin in her milk. Last fall I had such a patient with a suckling one month old. The mother had a severe form of tonsillar diphtheria. Her boy, six years old, developed diphtheria within twenty-four hours; but the baby nursed at the mother's breast and remained well. This supposition of antitoxin in the breast-milk may be incorrect or only a partial explanation. Recently S. Amberg found that all well nourished young infants have a high opsonic content of the blood; that the value of the opsonic content is in proportion to the nutrition of the infant; that breast-fed infants resist disease better because they are generally better nourished.

The Immediate Prophylaxis of Diphtheria.

This is generally considered to mean the administration of an immunizing dose of antitoxin to all exposed; but it should mean more. A physician showing a proper regard for other children, either wears a special hat and gown in attendance, afterward throroughly cleanses the exposed portions of his person, or the equivalent of these, or else gives an immunizing dose of antitoxin to all other children whom he attends

at the same time. There is no doubt about the possibility of carrying the disease in the clothes. Most physicians are willing to take the time for good surgical technic, but I believe many are not willing to take the time for good medical technic, of which this is a good example.

Quarantine. — In Portland, all patients receiving board of health antitoxin treatment are quarantined three weeks. Of course all cases of diphtheria should be quarantined, but I do not believe that all who receive antitoxin treatment should be long quarantined; for example, if in a suspected case antitoxin is given as a safeguard, and if by cultures the case proves not to be diphtheria, I think quarantine should cease. A careful board of health may reply that some physicians would fake cultures, that all cases of diphtheria would not be kept in quarantine. On the other side there is the fact that doctors, at times disliking to quarantine unnecessarily, will, to be more certain of diagnosis, let a mild case advance; and so while the use of board of health antitoxin compels quarantine, lives of patients will perhaps unconsciously be risked. I know of a case of a child three years old, living in a boarding house, which one would not like to quarantine unnecessarily. The diagnosis of diphtheria being uncertain a bacteriological examination was awaited. The bacteriological report was positive and twenty-four hours later the child died.

I believe really that such delays are faults of physicians and not faults of board of health rules; and, finally, that it is surely better to quarantine a number of families needlessly than to lose one patient through fear of it.

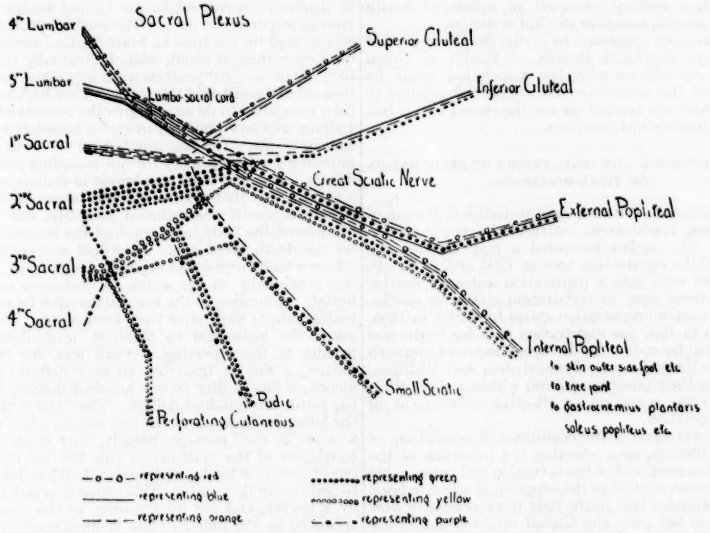
A SIMPLE METHOD OF RECONSTRUCTING NERVE PLEXUSES.

BY R. M. SMITH, M.D., AND E. W. TAYLOR, M.D., BOSTON.

A COMMON difficulty in the study of anatomy is the visualizing of relations. This is particularly true of the nervous system. However elaborate diagrams and plates may be, they fail to impress the important spatial relations of various structures. Dissection naturally comes to one's rescue in this respect, but even here the natural difficulties of continuing work in the dissecting room, after the early student years, are practically prohibitive. Any simpler resource, therefore, which will tend to impress upon the mind the relationship of correlated parts is of value, not only in teaching anatomy, but also in learning it. Hence have arisen various methods of more graphic representation than even the best illustrations can supply. Clay modeling, for example, has long been used with great success in the reconstruction of internal organs and, to some degree, in the study of the nervous system. Herring[1] describes in a convincing way the value of clay modeling as applied to the nervous system, and the extraordinary work of Florence R. Sabin in reconstructing the oblongata is well known to all students of the subject.

Perhaps the most elaborate attempt of this sort in teaching the finer anatomy of the central nervous system is described by Hardesty,[2] of the University of California. In a paper entitled, "A Class Model of the Spinal Cord," Hardesty describes in great detail a method of tracing the course of fibers in the spinal cord and lower oblongata by graphic methods. His plan is to make several cross sections of the spinal cord by means of wax plate models, accurately outlined from actual specimens. Stout wire is then used to connect the levels and to represent the various fiber tracts which may be easily distinguished by painting in different colors. By these means it is possible to build up in very considerable detail the essential internal structure of portions of the nervous system. In fact, the method has proved so practicable in Hardesty's hands that the students are expected personally to make such models as part of their training in the anatomy of the nervous system. It need hardly be said that the details which such a model brings out are not to be obtained through dissection, nor through the study of sections by the microscope, and yet these are the important points and far overbalance in significance to the clinician the descriptions which may be derived from textbooks and the ideas which are obtained from the ordinary course in descriptive anatomy.

A matter of considerable difficulty to the medical student is a proper understanding of the significance of nerve plexuses in relation, on the one hand, to segmental lesions of the cord, and, on the other, to disturbances in the distribution of peripheral nerves. In other words, the exact relation of nerve roots to peripheral nerves is not forthwith apparent and cannot be made so by dissection. Stimulated by Hardesty's very much more elaborate work, it occurred to us that a simple means of demonstrating by a graphic method the relation of nerve roots to peripheral distribution would be of value in teaching. In carrying out this general idea, the following means suggested themselves which are absolutely simple and at the same time demonstrate in striking fashion the points desired.



A piece of stiff cardboard is the first requisite. On this cardboard, preferably white, are specified the various nerve roots which enter into the composition of the plexus. Each of these nerve roots is represented by a single colored yarn or worsted, and by as many strands as the final distribution of the particular nerve root in the periphery may demand. As the various nerve roots, each represented by its color, break up in the plexus, the strands of worsted are separated and joined with those which come from other nerve roots according to the ascertained anatomical facts, ultimately emerging as the individual peripheral nerve containing fibers of the various nerve roots from which the special nerve has origin. At points where the plexus

[1] Herring: Clay Modeling in the Study of Anatomy. Jour. Am. Med. Asso., 1904, xliii, 454.

[2] Hardesty: A Class Model of the Spinal Cord. Bull. Johns Hopkins Hosp., 1906, xvii, 43.

divides, and at any others, for the purpose of securing the yarn to the underlying cardboard, we have found the most convenient means the use of very fine wire which may be looped over the strands of worsted and fastened on the under side of the cardboard. The result of this very simple device for making clear the components of peripheral nerves is entirely satisfactory. It is possible at once to determine precisely the nerve roots from which a given peripheral nerve springs and conversely to determine how wide a peripheral distribution any single nerve root has. A reference to the accompanying drawing will illustrate the method better than a more detailed verbal description.

The plan of reconstructing the plexuses, as outlined in what we have said, is so simple and carried out with so little expenditure of time, that it might well be used for an entire class. Furthermore, the materials necessary are so inexpensive and so easily procured that a large class could be provided at extremely small cost. The essential advantage of such a method of studying nerve supply is that the student does the work himself, referring naturally to anatomical textbooks for details of distribution. We have no question that once having worked out the plexuses in this way at first hand and unaided, a student would have a clearer and more practical conception of their structure than through many

Representing the six segments and their nerve roots which go to constitute the sacral plexus by variously formed lines, which in the actual model are much more graphically represented by different colored worsteds, it may easily be seen how the plan of the plexus may be worked out. For example, the inferior gluteal nerve is represented in the fifth lumbar and first and second sacral nerve roots, the great sciatic in all the nerve roots, excepting the fourth sacral, etc. On the other hand, should one wish to determine quickly what the peripheral representation, for example, of the first sacral nerve root is, it may forthwith be seen that the inferior gluteal, external and internal popliteal, and the small sciatic nerves derive elements from it. If carried out further, there is no difficulty in determining the segmental distribution of the sensory nerve supply, a matter which is apparently puzzling to the student.

hours devoted to textbook descriptions and even to dissection. The reconstruction of plexuses, in this manner, has also much practical importance from the standpoint of neurological diagnosis. It is not likely, after such individual work, that a person would forget the difference between a segmental or nerve root lesion and one in which the peripheral nerve was involved. It is not to be questioned, also, that the relatively small amount of work and study requisite to the correct construction of the plexuses would be of very material value in rendering the knowledge so obtained permanent.

Antituberculosis Dispensary at Bahia, Brazil. — The corner-stone of a dispensary for the aid of the tuberculous was recently laid at Bahia, with appropriate ceremonies, the governor of the state presiding. It is the work of the Bahia Antituberculosis League, which was organized last spring by the professors of the medical faculty and others.

Reports of Societies.

AMERICAN PUBLIC HEALTH ASSOCIATION.

THIRTY-FIFTH ANNUAL MEETING, HELD AT ATLANTIC CITY, N. J., SEPT. 30, OCT. 1, 2, 3 AND 4, 1907.

THE Laboratory Section held its meetings Sept. 30, under the chairmanship of DR. HIBBERT W. HILL, of Minneapolis, Minn.

The General Association met in the West Solarium of the Marlborough-Blenheim Hotel, with the president, DR. DOMINGO ORVANANOS, of Mexico City, in the chair. One hundred and seven applicants were elected to membership from different sections of America and Mexico.

There were two new sections organized at this meeting: first, a section composed of municipal health officers; second, a section on vital statistics.

A committee appointed to invite the Conference of State and Provincial Boards of Health of North America to affiliate with the association made its report, but this conference did not deem it prudent to affiliate with the association for the reason that it had separate and distinct functions.

THE OUTLOOK FOR A GENERAL SYSTEM OF REGISTRATION OF VITAL STATISTICS.

DR. CRESSY L. WILBUR, chief statistician, Bureau of the Census, Washington, contributed a paper on this subject. The author presented a map showing the extent of the registration area in 1895 and 1907. In 1895 there were only 8 registration states for deaths. In 1907 there were 15 registration states for deaths.

There were no registration states for births in 1895, and even in 1907 the registration area for births was represented by only a few interrogation marks on such states as Massachusetts, Pennsylvania and Michigan, indicating their possible addition within a short time, owing to the operation or effective enforcement of recent legislation.

Study was made of the conditions of population, as density, literacy, etc., affecting the extension of the registration area, and of the favorable and unfavorable circumstances relative to the adoption of effective laws. It was estimated that in the light of experience of slow progress in the past, the United States could hardly expect to have a satisfactory system of registration of vital statistics, including both births and deaths and covering the entire country, much before the middle of the present century, at which time, if all of the present agencies now effectively co-operating shall accomplish this result, the nation will have reached a place of advancement in this respect that would be quite equal to that occupied at the present day by Japan.

A standard certificate of death had been prepared by the association and the Bureau of the Census, and extensively employed with resulting advantage in causing uniformity of the data collected; yet many states and cities had continued to employ their old forms, whose variety was multitudinous, and offices that had adopted the standard blank had not hesitated to materially change it, so that the information obtained was frequently entirely different from what it purported to be when returned to the Bureau of the Census upon the actual standard blank.

The amazing thing about the way in which many deaths from tuberculosis were reported, as abscess of the chest, brain fever, marasmus, etc., was the general indifference of registration officials to the necessity of securing accurate statements of causes of death.

Finally, he said if the people of the United States wanted a thorough system of registration of vital statistics they could get it. It would not be necessary to wait fifty or sixty years for the slow adoption and enforcement of adequate laws. The process could be hastened, and without departing from the constitutional requirement that the primary control of registration should be by the states, and not by the federal government. If Congress, if the people of the United States, were really interested in this matter, and were determined that this thing should be done, the states would readily be brought into line.

DISCUSSION.

DR. JOHN N. HURTY, of Indianapolis, emphasized the importance of accurate registration of vital statistics. They have been trying to collect accurate statistics of deaths in Indiana, and now they are getting over 95% of deaths recorded, while the United States Census Bureau required but 90%. The medical profession, as represented by the Indiana State Medical Society, had done everything it could, while individually the members of the medical profession at large had not come forward and assisted in this work. They had, however, been compelled to do so and give the records of death. Indiana was now prepared to give a complete registration of births. The law was behind the state board, imposing a severe penalty for not recording births and deaths. If a dead body was buried in Indiana without a perrit, and that permit was not issued until a certificate of death was returned complete, the coroner disinterred the body, and required the necessary data on the death certificate. They had a special police officer whose income was dependent upon fees, and he was continually on the watch for instances of illegal burial. According to the law, births shall be recorded within twenty days after their occurrence. They had asked the legislature to make it immediate. The penalty of not reporting a death was, for the first offense, a fine of from ten to fifty dollars; for the second, a fine of fifty to one hundred dollars, and for the third, one hundred dollars. They had a clause in the latter stricken out at the last minute when the bill was on its final passage, namely, that upon a third conviction of the violation of this law for failure to report deaths or births, a physician shall lose his license to practice in that state. This clause was stricken out by a lawyer, and not by a doctor, as the clause was approved by the Indiana State Medical Society.

DR. QUITMAN KOHNKE, of Covington, La., suggested to the officials of the Census Bureau that a uniform system of laws be submitted to each state for adoption. Law was the main reason why mortality statistics were not the same in every state. He hoped the Census Bureau would assist the whole country in getting a uniform system of laws to make the statistics of one state comparable to those of another.

DR. HENRY MITCHELL, of Asbury Park, N. J., said that in an experience of about fourteen years in New Jersey, they had found that it was not a question of law, but one of enforcement of the law.

DR. WILBUR, in closing the discussion, said that the association had been co-operating with the Census Bureau for five years, first, in laying down principles on which a successful registration law could be constructed, and, second, in drafting such laws for adoption in various states. If registrars depended on the patriotic motives of physicians or midwives or anybody else to comply with the law, in regard to recording births and deaths, if they were not put in jail when they violated it, registration would be worthless. In Germany or France they had 100% of births and deaths.

SOURCES OF ERROR IN THE LABORATORY DIAGNOSIS OF DIPHTHERIA.

Dr. Hibbert W. Hill, of Minneapolis, submitted what was actual proof and what must be assumed to make a bacteriological diagnosis of diphtheria logical and a practical success. *First*, the finding of diphtheria bacilli in a culture taken by itself proved nothing except their presence in the culture. *Second*, granting that the culture was properly taken, the finding of bacilli proved their presence in the throat, etc., from which the culture was taken, nothing more. *Third*, the presence of diphtheria bacilli in the throat plus appropriate symptoms justified the assumption that the patient had the disease, the evidence being that from 98% to 99% of all patients showing this condition had the disease. *Fourth*, the presence of diphtheria bacilli in the throat, without symptoms, required further data as to exposure. If a clear history of the absence of exposure could be obtained, it was legitimate to assume that the diphtheria bacilli found were likely to be nonvirulent, the evidence being that 80% of such cases were not virulent. If exposure was established, a legitimate assumption was that diphtheria bacilli were virulent, and therefore, when present, might infect others who would come down with the disease in a short time, the evidence being that the infection obtained from a cilnical case was almost invariable. *Fifth*, failure to find diphtheria bacilli in a culture was about 90% conclusive of their absence in the throat. If a second culture be taken, and also proved negative, the two consecutive negatives taken together afforded about 99% conclusive evidence. If two or three or four negatives were obtained, the absence of diphtheria bacilli was established with direct finality.

DISCUSSION.

Dr. John N. Hurty asked whether it was not possible that a nonvirulent diphtheria bacillus in one throat might become virulent in another. For instance, the health officer might visit a school and find two or three cases of virulent diphtheria, and yet if cultures were taken from the throat of every child in the room, diphtheria bacilli would be found, but as these were making a good defense against the disease, it was assumed that the bacilli were nonvirulent. In Indiana they had been acting on the assumption that the bacilli were virulent when found in these children's throats. When found, action was taken immediately. If one went into a family to see a case of diphtheria, it was clinical diphtheria or laboratory diphtheria, and whichever it was, antitoxin should be used on all children in the household, giving them immunizing doses.

He had used antitoxin liberally whenever diphtheria existed, and felt that in several instances in his state he had stopped epidemics of the disease. For instance, in one county he rode twenty-seven miles, and in that time visited sixteen families, finding six cases of diphtheria. He immunized every child in each family, and this was the end of the diphtheria, in that there was no further spread of the disease. They did not inquire as to whether the children were infected with virulent or nonvirulent diphtheria bacilli, and he believed this was good practice to recommend.

Dr. William C. Woodward, of Washington, D. C., called attention to the distinction that existed between medical diphtheria and legal diphtheria. A year or two ago the question arose in the District of Columbia as to the exact status of a child in whose throat or nose diphtheria had been found, but who showed no clinical symptoms of the disease, and a wise corporation counsel decided that if diphtheria bacilli were found in a man's or child's nose or throat, that that man or child had diphtheria. The question of the presence or the absence of the clinical symptoms counted for nothing in law, and that a man or child was a danger to the community who had diphtheria, and should be treated as such. Whether that was going to hold in the case of diphtheria patients, he did not know.

Dr. B. Franklin Royer, of Philadelphia, was much impressed with the statement of Dr. Woodward as to what constituted legal diphtheria, and yet the speaker questioned if in a court of law one could prove legal diphtheria by finding the bacillus in accordance with bacteriological methods in the throat or nose cultures. These methods at present were snapshot, were not satisfactory to clinicians, nor to bacteriologists. The great trouble was that so many organisms were met with which closely resembled the diphtheria bacillus, it was with great difficulty it could be positively excluded. Those who dealt largely with bacteriology agreed that a negative test of virulence with a culture that had been injected into a guinea pig was the only reliable test which would exclude some of the forms of diphtheroid organisms, and the simple presence of an organism pronounced by a bacteriologist from his routine culture methods, such as were used in public health work, was not sufficient evidence.

A positive report that such an organism as the diphtheria bacillus was present would not be accepted in a court of law, if some one questioned whether it was a virulent organism or the true diphtheria bacillus. If its virulence had been tested, and it killed a guinea pig with typical lesions, it would be accepted.

Dr. Charles V. Chapin, of Providence, R. I., said that as a health officer he undertook to restrain a boy who had diphtheria bacilli in his throat from mingling with other children, but he was not sick, and the court decided that he did not have diphtheria. Disease was one thing, but infection with disease germs was another thing. He felt very sure that the courts would interpret the term disease as applying to a pathological condition of the human body. They would not apply the term disease to a condition in which there was the presence simply of the organisms which might cause disease, and when, for some reason or other, they did not cause disease.

Dr. J. J. Kinyoun, of Florida, said a great many health officers and the majority of physicians placed too much stress on positive tests or preliminary cultures. He thought that just as soon as they attached less importance to preliminary tests and more importance to discharge tests, the better it would be for patients. In other words, the free use of antitoxin would cure more cases of diphtheria and render the office of the health officer less difficult. As to what constituted diphtheria legally, he felt that the judge who rendered the decision referred to by Dr. Chapin was wrong, because if that generally held, health officers would have to abandon practically all quarantine measures.

Dr. William Bailey, of Louisville, said he did not appreciate fully the close distinction that was made between legal and nonlegal diphtheria. Whatever might be the judgment of a court, he thought that any child who had the bacillus of diphtheria in his throat ought to be put under control. He would not like a child of his to mingle with such a child, and even if it could be decided technically that in a given case the bacillus was nonvirulent, it might become virulent. On the same principle one might take a rag or cloth that had come in contact with a smallpox patient into court, and while the court would not decide, perhaps, that the rag had smallpox and could not be convicted, yet he thought it was wise to take care of the rag the same as he would a child who had the bacilli of diphtheria in his throat.

DR. CHARLES A. HODGETTS, of Toronto, Ontario, mentioned an industrial school in Ontario of 250 scholars, in which for two or three years, now and then, there were true cases of diphtheria which were isolated. Of this number over 50% of the pupils were found to be the carriers of diphtheria bacilli. Those found to be sick were given immunizing doses of antitoxin and were segregated. The school-teachers and children, however, grew tired of this segregation, and very soon the children were allowed to mix with one another. It would not surprise him if at any time cases of diphtheria were reported from that school. These cases should be dealt with in a rigid manner.

DR. HILL, in closing the discussion, said it was necessary to take action as soon as possible whenever the existence of diphtheria was suspected among school children.

CONTROL OF SO-CALLED MINOR INFECTIOUS DISEASES.

Papers were read on this subject by DRS. A. G. YOUNG, of Maine, and ALFONSO PRUNEDA, of Mexico City, in which the authors discussed measures for controlling whooping-cough, measles, etc.

DISCUSSION.

DR. GARDNER T. SWARTS, of Providence, R. I., said there was nothing more annoying than a lack of control of the minor infectious diseases. Health officers and physicians could not impress upon the public too strongly the importance of controlling measles and whooping-cough, for as long as these diseases were treated with indifference both by physicians and the people, so long would they continue to spread contagion. Even though they could not be altogether prevented, they could be checked in a measure. The sooner physicians impressed upon school authorities and teachers that these minor diseases were dangerous to the public health, and laws and ordinances were enacted to that effect, the better it would be for mankind.

DR. QUITMAN KOHNKE said the importance of the so-called minor infectious diseases depended on locality, environment and climatic condition. Each locality should be guided by the local importance of any particular disease, and should adopt such measures as were justified.

TYPHOID FEVER AT KNOXVILLE, TENN., AND ITS RELATION TO THE WATER SUPPLY.

MESSRS. ROBERT S. WESTON and RALPH C. TARBETT, of Boston, contributed a joint paper on this subject. The evidence was against the supposition that the water supply was a cause of the high death-rate from typhoid fever at Knoxville. The writers maintained that if the geographical distribution of each case for two or three years could be studied as it occurred, the causes of the disease would be shown and the remedy would suggest itself. Their studies show the importance of paying more attention to the hygiene of the household independently of the great problems of public water supply and sewerage. Undisinfected typhoid excreta and other infectious material which could become insect-borne should be destroyed and typhoid patients should be forced by education and law to protect their neighbors against infectious disease.

DISCUSSION.

DR. QUITMAN KOHNKE said that his experience in New Orleans bore out the opinion that typhoid fever there was in at least 90% of the cases brought from other places, notably summer resorts. Typhoid fever should be considered important wherever it occurred, and it would be competent in his opinion for the association to issue recommendations based upon those facts.

DR. JOHN A. MACDONALD, of Brandon, Manitoba, said that typhoid fever had been prevalent in Brandon and thereabouts for twenty-four years, every fall. Sometimes it would come on in August and run its course in epidemic form for two or three months. One thing very noticeable this year was the absolute absence of flies until about six weeks ago. It is a curious coincidence, if such it might be termed, that typhoid was absent until the flies appeared. During the greater part of the summer very few flies were seen and it seemed to him that this was a noticeable observation in connection with the possible dissemination of typhoid fever by flies.

DR. EDWARD V. HUG, of Lorain, Ohio, said that Lorain was one of the first cities to adopt the mechanical filtration method of dealing with water. For several years this city had no sewer system. This was prior to 1892, and during those years the death-rate from typhoid was about 44 per 100,000 population. During the past two years, 1906 and 1907, so far the death-rate had reached 34 per 100,000. But during these years the city had been building a new plant, with a capacity of six million gallons a day.

DR. HIBBERT W. HILL had seen outbreaks of typhoid fever beginning with the freezing of the water supply and terminating when the river, for instance, thawed. In a town in the Red River Valley, with a population of four thousand people, 10% of the inhabitants had typhoid fever due to a polluted water supply. The epidemic began when the river was frozen, but ceased when the river had thawed out again.

DR. HENRY D. PEASE, of Albany, N. Y., corroborated what Dr. Hill had said with reference to winter epidemics of typhoid fever due to the pollution of water supplies. He mentioned five or six epidemics of typhoid fever that had occurred, some in small towns, and some in large ones, which followed the course that was mentioned.

CONTACT INSPECTION.

DR. CHARLES V. CHAPIN, of Providence, R. I., said the valuable report on typhoid fever in our army during the Spanish war and the observations of the English in the Boer war indicated very clearly contact infection as the chief factor in camp typhoid. Jordan's report on typhoid fever in Winnipeg also laid great stress on this mode of infection, and many recent writers in Germany and America attached great importance to it. It was the author's opinion that the larger part of the typhoid fever in the United States to-day was caused in this way. Only a small part was due to infected water or milk, and still less to infected air.

There was ample room for improvement in the management of contagious diseases. We must teach those who had the care of the sick not to waste so much time on the invisible dry and dead micro-organisms of the air, but to use more soap and water on their hands. Better still, try not to infect the hands or clothes in the sick room. There was a great deal of unnecessary handling of the patient and of infected articles by health officers, physicians and nurses. By paying more attention to contact infection, isolation in the family and hospital would be easier and more successful.

UNCINARIASIS IN FLORIDA.

DR. J. J. KINYOUN undertook an investigation of this disease to ascertain the prevalence of the infection and to see how far the average practitioner would be interested in such an investigation and the eradication of the

infection. He examined the children of two orphanages in Jacksonville. There were 39 cases of the disease in all. Careful examination of all the cases showed that the children were undeveloped and were of low mentality. He contended that the majority of cases were infected through the skin, and a few through the alimentary tract. Although the latter could not be altogether excluded, the avenues of infection were far less than that of the skin. He urged that a systematic study of the prevalence of the disease in the state be undertaken.

HIGH ALTITUDES IN TUBERCULOSIS.

PROFESSOR WEINZIRL, of New Mexico, said that his observations had led him to conclude that the great changes in the daily temperature observed at high altitudes acted as a stimulant on patients, and this was the main factor in the high dry climate cure of tuberculosis. That dryness, altitude and sunlight were important mainly because they were instrumental in producing these great temperature variations which insured cold nights and refreshing sleep, while the stimulation produced a better appetite, better digestion and the assimilation of food, thus affording the consumptive strength for combating the disease.

EFFECT OF HEATING UPON THE DETERMINATION OF LEUCOCYTES IN MILK.

PROF. H. L. RUSSELL and MR. CONRAD HOFFMANN, of Madison, Wis., contributed a joint paper on this subject. In the methods heretofore proposed for the determination of the cellular content of milk, an important factor influencing the accuracy of the determination had been overlooked. It was found that pasteurized milks almost invariably showed a higher cellular content than unheated milks. The authors found that the heating of the milk to 70° C. for fifteen minutes increased the cellular content from 1% to 30 above that of the unheated milk. This increase was found to be most marked between 60° and 70°, the temperature at which the fat globule clusters were broken up to form a more or less homogeneous emulsion. Many cellular elements were normally entangled in these clusters, and were liberated only when the latter were broken up. That these cells were so enmeshed was clearly shown by allowing whole milk to separate by gravity and then examining the cream and skimmed milk thus obtained. The cream showed a very high cellular content as contrasted with that of the skimmed milk. When milk was first heated, the number of cells found in the cream was materially diminished, and those in skimmed milk increased. It was evident that the cellular elements were carried up with the cream, and unless the milk was heated, a large number would be drawn off with the supernatant fluid, and thus escape enumeration. Examination of this fluid from unheated and heated samples gave much higher results for the former than the latter. Heating of the milk prior to centrifugalization permitted of increased accuracy, as was evidenced from a large series of duplicate determinations, which showed an average variation of only 2.7%. It was accordingly deemed advisable to heat all milks, prior to examination for leucocytes, high enough to destroy the fat globule clusters.

DETERMINATION OF INTESTINAL BACTERIA IN MILK.

DR. DANIEL D. JACKSON, of Brooklyn, said a demonstration of the value of the lactose bile medium for determining the presence of intestinal bacteria in water had led to its use in the determination of bacillus coli in milk. The restraining action of the bile salts on growths of the numerous other species of bacteria in milk admitted of its use, whereas the Smith solution gave entirely unsatisfactory results for this purpose, due to overgrowths and to the production of gas by species other than bacillus coli. Contrary to expectation, it was found that when other species were present, the bacillus coli did not increase in number in milk, but gradually decreased so that the extent of fecal contamination could be measured. The range was found to fall within the same dilutions as in water analysis. A clean milk, or one that had been pasteurized, rarely gave the test for bacillus coli in the $\frac{1}{10}$ dilution. A carelessly handled milk would give the test in the 1 cc. dilution. A contaminated milk would give positive tests in the $\frac{1}{10}$, 1 and 10 cc. dilutions.

DIPHTHERIA DIAGNOSIS.

DR. B. R. RICKARDS, of Boston, referred to some of the factors which enter into the bacteriological diagnosis of diphtheria. The question of types on which a positive report should be given was discussed from both the standpoint of diagnosis and release, the question being raised that in some cases greater leeway should not be allowed in release cultures owing to the clinical evidence of the organism. The personal element still entered into diagnosis to a certain extent, but could and should be reduced as much as possible. It was better for the diagnostician to have no knowledge of the clinical data of a case until the bacteriological diagnosis was made, owing to the mental bias which might otherwise be produced. In testing diphtheria organisms for virulence, varying results in the virulence of organisms isolated from the same culture had been noted and further work along this line was very necessary.

The writer believed that there should be greater uniformity in the various laboratories as to what forms should be considered as positive for diagnosis and release, and he emphasized the necessity of further experimental work on most of the points regarding the value of co-ordinating diphtheria diagnosis and diagnostic procedures in general, in order that it might be placed on a standard basis.

THE DIAGNOSIS OF RABIES.

DR. A. W. WILLIAMS, of New York City, said that three methods had been used in helping to establish the diagnosis of this disease. First, animal inoculation; second, sections for the presence of small-celled accumulations about the blood vessels and ganglion cells; third, sections and smears for the presence of the so-called Negri bodies. The second method had fallen largely into disuse, because the histological changes upon which its value depended had been shown to be nonspecific for rabies. The first method was used as a decisive test when results from the third method were doubtful. The results obtained from the use of the third method were as follows: (1) Negri bodies demonstrated, diagnosis rabies. (2) Negri bodies not demonstrated in fresh brains, diagnosis very probably not rabies. (3) Negri bodies not demonstrated in decomposing brains, diagnosis uncertain. (4) Suspicious bodies in fresh brains, diagnosis probably rabies.

The demonstration of the Negri bodies by smears was the most rapid and efficient method so far published. Improved technic had lessened the number of suspicious or uncertain cases.

He described the technic of the smear method at present in vogue in the research laboratories of the New York City Health Department.

MILK.

There was a symposium on this subject. PROF. E. B. VOORHEES, of New Brunswick, N. J., said the public

should realize that even at twelve cents good milk was the cheapest and best nourishment it was possible to buy. To produce pure milk at the present selling price in the big cities at a profit to the farmer was impossible. The most careless dairyman could not turn out even his inferior grade of milk for less than 4.7 cents a quart, while an average cost of production of five cents was the lowest practical rate. A very small additional expense in the price of milk was necessary to guarantee absolute purity and general quality of milk.

PROF. C. B. LANE said that the majority of dairymen would prefer to sell only the best milk procurable, if the public would pay for it, and he declared that the general public was quite willing to stand the higher rate. More stringent legislation was needed to procure permanent results. At the present time the man who added water to the milk was fined. Generally, the man who sold impure milk went scot-free, and this despite the fact that the latter was much the greater menace. He advised national laws modeled after the British statutes which permit a consumer to sue for damages a dealer who supplies him with impure milk.

DR. THOMAS DARLINGTON, of New York, advocated that each community should look after its own milk supply. He recommended systematic and constant inspection, in the first place, and, in the second, the prevention of the sale of any milk which was unwholesome and adulterated. Every dairy and every creamery supplying the city of New York had already been inspected. As for preventing the sale of unwholesome milk, he had only to mention that the Court of Special Sessions a day or two ago had 260 cases before it. Gastro-intestinal diseases had been markedly reduced since the proper inspection of milk had been enforced.

PROF. R. A. PEARSON, of Cornell University, discussed the protection of milk under five headings, namely, health of the cow; cleanliness of the cow and her surroundings; condition of the utensils in which the milk was handled; cleanliness of the employes, including their health, and the cooling and storing of the milk.

Speaking of the tuberculin test, he said that when farmers clearly understood its true value, they would want this test made. When they were shown by demonstration that which they failed to understand, they were anxious to have this test. Very many milk producers were honest and anxious to do what was right. They needed instruction. A campaign of education had been begun. It needed support. Every milk producer should have the opportunity to know the latest concerning his business, then many of them would make the desired improvements in their dairies, and the realization of ideal dairying would go hand in hand with the necessity of enforcing laws.

SOCIAL ETHICS AS INFLUENCED BY IMMIGRATION.

DR. PETER H. BRYCE, of Ottawa, Canada, said that immigrants were pouring into the United States and Canada at the enormous rate of a million and a half annually, and it was a grave question whether this tremendous influx of human flotsam and jetsam would be assimilated or continue a foreign mass and a menace to the nation. Invasion of foreign labor had driven American girls from mills and factories to a higher plane of employment. But the standard of intelligence was too low for foreign competition to seriously affect American mechanics. The mental status of immigrants to-day was higher than that of many years ago. Steamship companies forced by close competition expended enormous sums in new ships, deliberately seeking the immigrant as a means of making up their losses. This was one of the evils of the problem with which America and Canada had to contend.

The Mexican delegates reported that their country was constantly raising the barriers against undesirable immigrants, and urged that the United States government at Washington formulate a new code of laws that might be adopted also by Canada and Mexico.

TRACHOMA AND IMMIGRATION.

DR. AUGUSTIN CHACON, of Mexico City, said that immigrants to that republic had been the cause of an epidemic of this disease of such serious proportions that it would be absolutely necessary for the government to adopt radical measures for the protection of the country.

OPHTHALMIA NEONATORUM.

DR. F. PARK LEWIS, of Buffalo, presented this subject to the association. A committee was appointed to confer and co-operate with a like committee of the American Medical Association and with the committees appointed by other medical societies, to prevent this disease.

OFFICERS.

The following officers were elected for the ensuing year: President, Dr. Richard H. Lewis, of Raleigh, N. C.; First Vice-President, Dr. Gardner T. Swarts, of Providence, R. I.; Second Vice-President, Dr. Chas. J. Hodgetts, of Toronto, Ontario; Third Vice-President, Dr. Manuel Iglesias, of Mexico City; Treasurer, Dr. Frank W. Wright, of New Haven, Conn.; Secretary, Dr. Chas. O. Probst, of Columbus, Ohio.

Winnipeg, Manitoba, was selected as the place for holding the meeting in 1908.

Book Reviews.

A Manual of Diseases of the Nose, Throat and Ear. By E. B. GLEASON, M.D., LL.D., Clinical Professor of Otology in the Medico-Chirugical College, Philadelphia. Illustrated. Philadelphia and London: W. B. Saunders Company. 1907.

This adds another to our list of students' condensed manuals of the nose, throat and ear. In the process of condensing, some important subjects have especially suffered. Nasal polypus, for instance, is finished in two small pages, papilloma of the larynx in one, and acute tonsillitis, which is combined into one disease with peritonsillar abscess, in four. Although everything is in outline, other parts of the book suffer less from brevity. Gleason's name is widely associated with an operation for correcting septal deviations, and his original work in this direction makes this chapter valuable. In other subjects the opinions and practice of the author are interesting. He has not abandoned the use of the nasal saw. He says little about the dissection of deeply seated tonsils, and is conservative in the symptoms and treatment of adenoids. The pathologist may object to myxoma as a name for a polypus, and to mycosis for keratosis, and perhaps to the aborting of an acute tonsillitis by washing out the crypts, and the surgeon to the description of Killian's frontal sinus operation. The book is

convenient and attractive, and on the whole conservative and compact. It ends in a long list of prescriptions for both local and general treatment.

A Textbook of Clinical Anatomy. For Students and Practitioners. By DANIEL N. EISENDRATH, A.B., M.D., Adjunct Professor of Surgery in the Medical Department of the University of Illinois (College of Physicians and Surgeons); Attending Surgeon to the Cook County Hospital, Chicago. Second edition, thoroughly revised. Illustrated. Philadelphia and London: W. B. Saunders Company. 1907.

The second edition of this book appears in essentially the same form as the first. The text has been revised, and a certain number of new illustrations added. The idea of this work is altogether to be commended in its attempt to render practical the more theoretical study of descriptive anatomy. It may well be expanded far beyond its present scope, in relation particularly to the nervous system. The book has apparently been so favorably received that we hope its author may see fit to extend it further in subsequent editions.

Pediatrics. The Hygienic and Medical Treatment of Children. By THOMAS MORGAN ROTCH, M.D., Professor of Pediatrics, Harvard University. Fifth edition, rearranged and rewritten. Illustrated by numerous engravings in the text and by colored plates. Philadelphia and London: J. B. Lippincott Company.

This, the fifth edition of this well-known work, is, like each of its predecessors, an improvement on the one before. The book has been arranged, revised and brought well up to date. The divisions on "The Care of Premature Infants," "Feeding," "Diseases of the Gastro-enteric Tract" and "Diseases of the Nervous System," as well as several others of minor importance, have been rewritten. That on "Infant Feeding" is without question the most complete and satisfactory to be found in any textbook. That on the "Diseases of the Gastro-Enteric Tract" is based on the classification of these diseases recently adopted by the Department of Pediatrics in the Harvard Medical School. This classification is based on etiology, and is a decided advance on the old system. The various divisions, as in previous editions, are of rather unequal merit, that on the "Diseases of the Nervous System," in spite of having been rewritten, still being rather unsatisfactory. The divisions treating of the "Infant at Term" and "Normal Development" are still unique in their completeness and accuracy.

While it would be easy, as with every book, to criticise many minor points, it is difficult to find anything of importance with which to disagree. The treatment in general is rational and satisfactory. The book, as a whole, is of great merit. No one interested in the care and feeding of infants and in the diseases of infancy and childhood, can afford to be without it.

Insanity and Allied Neuroses. A Practical and Clinical Manual by GEO. H. SAVAGE, M.D., F.R.C.P., Late Physician and Superintendent of Bethlehem Royal Hospital, Lecturer on Mental Diseases at Guy's Hospital, etc., with the assistance of EDWIN GOODALL, M.D. (London), F.R.C.P., Medical Superintendent of the Cardiff City Hospital for Mental Diseases, etc. Pp. 662. Chicago: W. T. Keener & Co. 1907.

This book is a revised edition of Savage's individual work published originally in 1884. Although it is enlarged by seventy-six pages and otherwise revised, we cannot follow the authors in the claim that it contains all the essentials with which the medical student is required to be familiar now-a-days. In the endeavor to bring it into line with recent advances in psychiatry, four pages on dementia precox and manic-depressive insanity and various plates have been inserted, a scheme for the examination of cases of insanity, suspected or actual, is appended, a few chapters are partially rewritten or rearranged and various minor changes are made, but there still remains a flavor of bygone conceptions of the disease. Perhaps because of the difficulty of covering so large a field in a manual, some subjects of importance to the general physician are inadequately treated, the psycho-neuroses, for example, and confusional conditions receive scant attention as such. In spite of these deficiencies, there is much that is valuable and instructive in the book which is plainly the result of a rich and varied experience, utilized by a keen observer and a wise and resourceful clinician. A great many cases are introduced. They are interestingly described and should go far toward fixing the symptomatology of the disease in the student's mind. What is said also regarding certain borderland conditions, particularly those of moral defect, as well as the thorough and practical methods of treatment employed to meet acute conditions, is sound and helpful.

Manual of Obstetrics. By A. F. A. KING, A.M., M.D., LL.D., Professor of Obstetrics in the Medical Department of the George Washington University, Washington, D. C., and in the University of Vermont, etc. Tenth edition, revised and enlarged. Pp. 688, with 301 illustrations and 3 plates. Philadelphia and New York: Lea Brothers & Co. 1907.

Since the last edition in 1903, the book has been materially improved. The chapter on fecundation and nutrition of the embryo has been practically rewritten, many changes made in the chapters on pelvic deformity, cutting operations on the mother, mutilating operations on the child, placenta previa and puerperal septicemia. The chapter on toxemia gives the erroneous idea that the kidneys are primarily at fault, and nowhere is mentioned the frequent occurrence of pyelitis as a complication of pregnancy. Altogether it is an excellent manual and more than a manual. It is commendable to the practitioner, perhaps, to even a greater degree than to the student.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, NOVEMBER 21, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

SCIENTIFIC ACCURACY AND THE IMAGINATION.

LE BON, in his work "The Crowd, a Study of the Popular Mind," tells of a crew shipwrecked upon a raft, who kept eagerly scanning the horizon for a sail. After some days of watching one of them declared he saw a sail; unquestionably he saw something, and so desperate was the hope of his companions, that they all agreed with him the thing to which he pointed was a vessel which could rescue them. When they came upon it, however, they found it a tree which had evidently been uprooted in an equatorial storm. Tuke, in his admirable work on "The Influence of the Mind Upon the Body," relates how a boy who had on an afternoon seen a hanging, which had naturally much affected him, took a stroll along the country road in the evening of that day. He presently saw projected against the sky the gibbet of the afternoon and the criminal suspended from it. He ran home dreadfully frightened, to find that a cord dangling over the brim of his hat had been metamorphosed by his overwrought imagination into the aërial gallows.

These are instances — hundreds of the same sort might be cited — of delusions entertained by the unsophisticated, the highly emotional and the unscientific in which such aberrations are excusable enough. We who have been trained in science are so prone to consider such delusions the exclusive property of spiritualists, theosophists, geniuses and other highly imaginative people, that we feel distinctly humiliated when we learn that men of scientific reputations have entertained such psychic aberrations. As, for instance, when the telephone was invented, a lecturer who was giving a public exhibition of the apparatus clearly and repeatedly heard the notes of a trumpet which he had arranged to be played at the other end of the wire. Yet none of his audience could hear them; and for the very reason that the trumpeter had made a mistake in the day, and was not in his place at all. A very modern instance of "illusion caused by a species of autosuggestion based on preconceived ideas" is furnished by the n-rays which all competent men agree to-day never had any existence at all.

The Manchester *Guardian* related how these rays were discovered by Professor Blondlot, of Nancy, in 1903; he described them before the French Academy of Sciences, who gave him a gold medal for his discovery. During the next three years 176 original papers were published concerning them. Blondlot's observations, which were surely made in good faith, were in turn confirmed by such well-known physicists as Charpentier and Bequerel. These rays were said to be given off by almost all substances when in a state of strain; a tempered steel bar, a Nernst lamp, and even human nerve and muscle would emit them. The rather fanciful suggestion came that if a certain radiation were given off by our bodies, according to their degree of activity, our thoughts might possibly be photographed, "thoughts being only brain rays." The n-rays, stated French investigators, could be reduced or removed by anesthetics; for that matter, a tempered steel bar could be chloroformed into quiescence. Following upon this the invitation came naturally enough for us "to revise some of our notions on the difference between the inorganic and the organic." The n-rays were held to be even more wonderful than the x-rays or radium. Oddly enough, however, the n-rays did not, like the Röntgen rays, affect either the spectroscope or photographic plates. Admittedly they were rather baffling and elusive; but they had one physical effect upon which experimenters largely relied — their power to intensify the brightness of a light. A marked increase of luminosity was perceptible when an n-ray was directed upon a spark; or if a bar of tempered steel were held near a clock in a dark room, it was supposed to be possible to read the time.

In time Blondlot's experiments were confirmed and even extended outside France; yet many scientists utterly failed from the first to observe any of the phenomena described. English and German investigators became particularly skeptical, and rather absurdly a dispute arose, which

increased in bitterness and became quite akin to our own famous *row upon the Stanislaus*. Two camps were formed — the Latin and the Teutonic; and compliments increased in warmth as they lost in polish. The French imputed prejudice and animosity to their foreign critics; it was suggested that the rays could be distinguished only by the more sensitive and delicate brain of the Latin, while on the other hand nothing could be expected of the British brain, muddled as it is by the London fog, nor of the beer-befuddled German psychism. The matter in dispute threatened to place itself beyond the bounds of demonstration. Presently, however, the coolest French scientists gradually began to suspect that if no results could really be obtained in England and Germany, the explanation of the French experiments must be subjective and psychological rather than objective and physical. Finally, the *Revue Scientifique* settled the question in a very simple way. It was proposed that several small boxes of exactly similar appearance, some containing pieces of lead, others of tempered steel, should be sealed; and Blondlot or his assistants were to decide which of the boxes contained the active material. Blondlot refused this test, saying that "the phenomena were far too delicate for such a trial"; and he left "every one to form his own opinion on the n-rays, either from his own experiments or from his confidence in those of others." Thus was the dispute transferred from the realm of fact to that of opinion, experimentation ceased, and so far as science is concerned the incident was closed.

We repeat, such incidents as these are rather humiliating to the scientific temperament; fortunately they are extremely rare. We feel it pertinent to emphasize, however, that science is knowing; it should always be "certainty grounded upon demonstration"; it should always be self-poised and well judging; and its votaries should be absolutely free of autosuggestions and haphazard conjectures incapable of verification.

EMPLOYMENT FOR THE HANDICAPPED.

Very frequently, both in private and hospital practice, the physician is confronted with a patient unable from disability, the result of accident or disease, to return to his former occupation. Perhaps even a larger group is formed by those still able, for a time, to carry on their previous work, yet if they do so, it would mean a speedy return of the condition which has first brought them under the physician's care. What is to be done with such patients? The answer is, find them work of such a character that for it their particular disability forms no handicap. A one-legged man can do many varieties of hand work, and compete on equal terms with his more fortunate fellow worker. A cardiac case is competent to do light sedentary work with no injury to himself. Many more examples of this kind could be given, but it is not necessary, since on a moment's thought the situation is very obvious.

To find a vacancy in that particular kind of employment, for which the handicap of a given individual does not constitute a preventive disability would often prove a very difficult undertaking for the individual physician or charity worker. What is needed is some form of clearing house, in which the proper adaptation of these laborers to some sort of work can readily be made. About eighteen months ago the Charity Organization Society of the city of New York undertook this function through its Employment Bureau for the Handicapped. This has proven eminently successful in its working, for during the past eight months this bureau has placed an average of more than one out of two applicants, no mean record for any form of employment bureau. This does not mean that the employer has received a damaged article, for the bureau is careful to so select those they recommend that their disability does not hamper them for the particular work required, and this fact has been recognized quickly by those seeking workers. The range of activity of the bureau is indicated by the positions found for applicants, such as domestic servants, factory workers, janitors, messengers, country laborers, clerks, porters, watchmen, drivers, elevator men, guides, telegraph operators, needle workers, etc. The wages of these positions ranged from $3.00 to $20.00 per week, the average being $8.36.

That this bureau has proved of great usefulness in New York is not to be questioned. Moreover, in any large city there is an extensive field for such a bureau, and its organization would materially help the medical man whose labors bring him into contact with the middle and lower classes of the population. It is hoped that many other cities will imitate the plan now in operation in New York. It is a form of charity work highly to be commended for its practical usefulness.

MEDICAL NOTES.

Women Physicians in London. — Within the past year, according to the *New York Medical Journal*, eighteen students of the London School

of Medicine for Women passed the M.B. degree of the University of London, which is the highest degree obtainable in England. Four took the M.D. degree, and one the M.S. degree, which is the hardest examination given in surgery.

RETIREMENT OF PROFESSOR POLITZER. — Dr. Adam Politzer, for forty-six years director of the Vienna clinic for ear diseases and professor of otology in the university, has recently resigned his position. The occasion was made one of some formality. His last lecture was largely attended by physicians, by his present and former assistants, and also by representatives of foreign otological societies in Europe and America. Among other honors conferred upon him was honorary membership in the American Medical Association. Professor Politzer is succeeded by Professor Urbantschitsch, who up to this time has been director of the ear department of the Vienna polyclinic.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Nov. 13, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 46, scarlatina 28, typhoid fever 10, measles 25, tuberculosis 31, smallpox 0.

The death-rate of the reported deaths for the week ending Nov. 13, 1907, was 17.71.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, Nov. 16, 1907, was 185, against 203 the corresponding week of last year, showing a decrease of 18 deaths and making the death-rate for the week 15.83. Of this number 98 were males and 87 were females; 177 were white and 8 colored; 124 were born in the United States, 52 in foreign countries and 9 unknown; 48 were of American parentage, 110 of foreign parentage and 27 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 52 cases and 1 death; scarlatina, 37 cases and 0 deaths; typhoid fever, 13 cases and 1 death; measles, 22 cases and 1 deaths; tuberculosis, 31 cases and 15 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 27, whooping cough 1, heart disease 20, bronchitis 2 and marasmus 3. There were 17 deaths from violent causes. The number of children who died under one year was 37; the number under five years, 53. The number of persons who died over sixty years of age was 50. The deaths in public institutions were 62.

There was 1 case and 0 death reported from cerebrospinal meningitis during the week.

NATIONAL HEALTH BUREAU. — A committee of one hundred of the American Health League held a conference at Yale University, New Haven, Nov. 17, in the interests of the extension of federal regulation of public health. Prof. Irving Fisher read a paper on the subject, "How to Double Working Efficiency by Diet." Dr. J. N. McCormack also spoke.

SOUTH BOSTON ANTITUBERCULOSIS SOCIETY.— The South Boston Antituberculosis Society, of which Dr. Edward A. Tracy is president, and Dr. William J. Sheehan, secretary, proposes to give practical talks on tuberculosis every month throughout the winter at the Municipal Court building, corner of Dorchester and Fourth streets, South Boston, at 8.15 P.M. The public is invited.

ENFORCEMENT OF LAW RELATING TO DISTRIBUTION OF DRUGS. — It is reported that four arrests have recently been made of men found distributing samples of a so-called new cough medicine in one of the sections of Boston. The last legislature passed a law prohibiting the distribution of drugs in this manner; these arrests are the first that have been made under the law.

ADVISORY COMMITTEE, NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY. — Dr. E. E. Southard, Assistant Professor of Neuropathology at the Harvard Medical School, has been appointed a member of the Permanent Advisory Committee of the National Association for the Study of Epilepsy. The other members are Dr. L. Pierce Clark and Dr. Adolf Meyer. The objects of this committee are "to further the co-ordination of scientific and research work in epilepsy," and "to act as advisors for any workers in epilepsy who choose to apply to them."

OFFICERS, BOSTON MEDICAL LIBRARY.— At the annual meeting of the Boston Medical Library, held Tuesday, Nov. 12, 1907, the following officers were elected: President, Dr. George B. Shattuck; Vice-President, Dr. F. I. Knight; Treasurer, Dr. W. H. Prescott; Secretary, Dr. O. F. Wadsworth; Librarian, Dr. J. W. Farlow. Committee on Library and Finance, Dr. C. P. Putnam; Committee on Medical and Social Meetings, Dr. W. H. Smith; Committee on Membership and Elections, Dr. A. K. Stone.

Outdoor Camp for Tuberculosis. — The outdoor camp for tuberculosis at Mattapan, after a most successful season, will be forced to end its work unless certain financial support is forthcoming. A committee of patients has been formed with the object of soliciting further funds. The Boston Association for the Relief and Control of Tuberculosis has already maintained the camp three additional weeks, but six weeks still remain before the city authorities will be ready to take over the work. It is very important for many of the patients that the treatment be continued, and inasmuch as the amount necessary to maintain the camp is only $1,600, it seems altogether probable that it will be secured. Contributions may be sent to Mr. George S. Mumford, 4 Joy Street, Boston.

NEW YORK.

Inspection of Dairies. — A party of city health officials, including President Darlington, Health Officer Doty, and Dr. Russell Raynor, chief sanitary inspector, have been making a tour of inspection of the dairies in a large portion of the state, going as far as Oswego, and report the sanitary conditions as a rule much improved over those of last year.

Purity of Vaccine Virus. — Reports having again emanated from Brooklyn that school children had died from tetanus as the result of impure vaccine matter being employed by inspectors of the Health Department, President Darlington has come out in an emphatic denial, in which he attributes these strictures to the opponents of vaccination. "From time to time," he says, "such stories crop up, and after investigation they are found to be baseless. The virus used by the Board of Health is supplied by Dr. Huddleston, who is also secretary of the Academy of Medicine; and his name alone should convince the skeptics. Two hundred thousand school children are vaccinated annually, and the wounds, if not properly cared for, may become inoculated, just as any other wound might be. In every case the virus used is uniform and invariably pure, and our process of vaccination has exterminated small-pox in New York."

Death of Prof. Lucian M. Underwood. — Lucian M. Underwood, Torrey Professor of Botany in Columbia University, Chairman of the Board of Scientific Directors of the New York Botanical Garden in Bronx Park, and a Councillor of the New York Academy of Sciences, committed suicide at his country home at Redding, Conn., on Nov. 16, while suffering from melancholia. Prof. Nathaniel L. Britton, who was his predecessor in the chair of botany at Columbia and who is now director of the New York Botanical Garden, gives the following high estimate of his rank as a botanist: "In his work, Professor Underwood stood at the very head of his profession in the United States, and was one of the best known men in his line in the entire world."

A Verdict of $20,000. — At Flushing, Borough of Queens, on Nov. 13, in a suit for $75,000 damages against the General Chemical Company of Laurel Hill, Long Island, for the loss of his eyesight and disfigurement of his face, John L. Muller, an employee of the company, was awarded a verdict of $20,000 by the jury. The injuries, which were received in September last, were due to an escaping flow of sulphuric acid.

Work of the Seaside Hospital. — The annual meeting of St. John's Guild was held on Nov. 12. The reports showed that during the past summer, 36,816 mothers and children were carried on the trips of the floating hospital, and 7,077 patients treated at the Seaside Hospital at New Dorp, Staten Island. The average stay of the patients in the hospital was eleven days. The president, John W. Weed, announced that owing to the inability of the managers to raise a fund of $25,000 which it had been hoped would be subscribed for the purpose, it had been found impossible to keep the Seaside Hospital open during the winter this year. Last winter the work of the hospital was carried on with great success, 480 patients being treated during an average of thirty-one days, while there was constantly a waiting list of applicants. Duff G. Maynard exhibited stereopticon views showing the work of the floating hospital and of the Seaside Hospital in summer and in winter, and said that the greatest need in New York City at the present time was accommodations for convalescents. After the critical period of their illness, patients were sent out from the crowded hospitals in order to make room for others, and serious results often occurred in consequence of this premature discharge. In London, in a radius of two miles, were several hundred convalescent homes, while in the same radius in New York there were only three.

Conference of Charities and Correction. — The annual State Conference of Charities and Correction was held at Albany on Nov. 13 and 14, at which interesting reports and addresses were made by Dr. Edward B. Angell, neurologist to the City Hospital, Rochester, Dr. Adolph

Meyer, director of the Pathological Institute of the New York State Hospitals for the Insane, and others. In speaking of the saving of life which was gradually being effected, Dr. Angell called attention to the fact that while in New York City in 1876, out of 125,816 infants and young children, 3,632, or 28.86 per thousand, died from gastro-intestinal disease, in 1906, among 282,424 of the same class of subjects, only 3,354, or 11.87 per thousand, died from this cause. Dr. Meyer said that of the 27,102 patients now under the supervision of the State Commission in Lunacy, over one thousand had committed criminal offenses before their committal to institutions for the insane, and he recommended that every case of suspected mental disorder should be required to be reported to the commission in lunacy in the same way that infectious diseases are now reported to boards of health. In speaking of the lack of adequate accommodations for the insane in the state hospitals he stated that at present these institutions in the Metropolitan District, with 12,328 patients to care for, had a satisfactory capacity of less than nine thousand five hundred. Having complimented New York City in its efforts to provide for defective children in the public schools, Dr. Meyer said there still remained a deplorable number of children whose only salvation lay in removal from inadequate homes to schools where, under intelligent management, they could be brought to a certain degree of usefulness to themselves and others.

5. HAUBOLD, H. A. *Rupture of the Liver; Operation, Death.*

2. Einhorn describes the latest results obtained by him from the use of the bead test for ascertaining the digestive functions. He divides his cases into two groups: diseases of the digestive tract, and diseases of other organs. Sixty-eight cases in all constitute this series. He concludes that the bead test gives a true picture of the digestive condition, a worse state of digestion existing at the height of a disease than in convalescence. Results are influenced by personal idiosyncrasy. Marked digestive disturbance is found in barely half the cases of achylia gastrica, in delirium tremens, in grave cases of gastro-enteritis, and in typhoid fever. Diminution of starch digestion is often found, while disturbance of proteid digestion is rare. In purely nervous affections, pure colitis and constipation, digestion is good.

3. Hallberg recommends the following modifications of the Federal Food and Drugs Act in all state legislation: (1) Exemption from the label requirements for the articles of the United States Pharmacopeia, and the National Formulary, and physicians' prescriptions. The federal act now requires that all medicines containing alcohol and a number of potent and habit forming drugs, shall show on the label the amount of such drug contained. The articles of the United States Pharmacopeia and National Formulary necessarily conform to known standards. Physicians' prescriptions are not usually subject to interstate commerce and are of a confidential character. (2) Articles of the United States Pharmacopeia and National Formulary must conform to the requirements, although if feasible or desirable, the preparations may differ in color or flavor from the National Formulary formula if so stated on the label. Now under the federal law articles of United States Pharmacopeia and National Formulary may differ from the requirements if so stated on the label.

6. In Norway, from 1903 to 1905, there were 1,053 cases of acute poliomyelitis with 145 deaths. These cases have occurred often in small epidemics, and several cases have occurred in the same family. However, in the rather numerous cases in Christiania in 1905 and 1906, careful investigations did not demonstrate any connection between the cases. From the various epidemics the writers examined 19 cases post-mortem. There were no essential lesions outside of the nervous system. The inflammation apparently commences in the pia mater (often only demonstrable microscopically) with a probable simultaneous infection of the cerebrospinal fluid, and extends to the cord along the vessels. The pathological changes are always more extensive than would be suggested from the clinical signs. Even in the mild cases

with a very limited paralysis, involvement to some extent of the whole cord, and usually slightly of the basal ganglia and the cortex, was found. Certain cases of Landry's paralysis, of myelitis and probably of encephalitis should pathologically and etiologically be placed in the same class with ordinary acute poliomyelitis. The writers were unable to find any anatomical evidence to show relationship between acute poliomyelitis and acute multiple neuritis or epidemic cerebrospinal meningitis. They believe poliomyelitis is due to a specific virus. In three of their cases they found in the cerebrospinal fluid a diplococcus or tetracoccus similar to the organism previously described by Geirvold as the causal organism of this disease. This organism differs from the meningococcus of Weichselbaum. [R. I. L.]

5. DUNTON, W. R. *Mrs. Packard and Her Influence upon Laws for the Commitment of the Insane.*

2. Calvert hardened the cadavers of two individuals, who at the time of death had pericardial effusions. From transverse sections he concludes that the position of the heart in pericarditis depends on the size of the heart, which in turn depends on the stage of compensation. In normal compensation the heart is in relatively normal position. In failing compensation the heart becomes progressively smaller and more posterior. The apex is in normal position or displaced backwards and slightly to the right.

4. Emerson reports two cases who during the course of typhoid fever developed a very severe anemia with very many blasts, a very high leucocytosis (50,000 to 80,000) with 70% to 90% of polynuclear neutrophiles and a fairly large number of typical neutrophilic myelocytes. One case had a rather insignificant intestinal hemorrhage, followed by a period of hypothermia for three days. The other case apparently had a considerable hemorrhage. Both cases were fatal. Only one autopsy was permitted. In this case the bone marrow was red and contained typhoid bacilli. [R. I. L.]

6. JAMES, R. R. *Two Cases of Acute Spreading Gangrene, with a Note on Their Bacteriology.*
7. HANN, R. G. *A Case of Erythromelalgia.*

1. Hector Mackenzie has made an examination of the abdomen of nearly 4,000 people in regard to mobility of the kidneys. He is of the opinion that minor degrees of mobility are of trivial importance. Two thousand eight hundred and one females of all ages were examined; in 16% the kidneys were palpable only, and in 18.4% they were not only palpable but freely movable. In 1,067 males of all ages there were 2.3% of palpable kidneys and 1% of movable kidneys. Under twelve years he has met with no case in which the kidneys were movable. His figures agree very closely with those of Glénard, who examined 4,215 patients. He believes that the influence of child-bearing on the production of movable kidney is not very great, and that the influence of tight lacing as a cause of this condition has been exaggerated. Sex seems to be the most important factor, and absorption of the perirenal fat another important influence. Out of 515 cases with the high degree of mobility no fewer than 411 had no symptoms at all. As to treatment, a spring truss properly applied he has found more effective than belts and other cumbersome forms of apparatus. The improvement of general condition is very necessary. He believes that a long, careful medical treatment should be given before operative measures are resorted to.

4. Raw recommends the following measures for the administrative control of tuberculosis: (1) municipal dispensaries with notification of all "open" cases; (2) health visitors; (3) regulations against tuberculous persons handling food; (4) inspection of milk and meat; (5) improved dwellings and ventilation; (6) destruction of expectoration; (7) general sanitary measures; (8) disinfection of houses after death of tuberculous patients; (9) inspection of hotels and boarding houses; (10) separation of children from consumptives, with compulsory notification if necessary; (11) isolation of advanced cases; (12) hospitals for treatment; (13) voluntary notification. 4. Russell gives a paper with numerous illustrative cases on the indications for operation in cases of intracranial tumor. Operation may be recommended in some cases in the hope of effecting a cure; in these certain considerations influence this question, viz., (1) whether or not accurate localization of the tumor is possible; (2) although the tumor may be accurately localized, it may be in such a position as to render the chance of its successful removal very slight; (3) the tumor may be of such a nature, malignant or otherwise, that a complete cure is not to be expected. In operations to relieve the symptoms and prolong life the indications for and against trephining must be carefully weighed. The importance of saving sight by relieving intracranial pressure can hardly be overestimated.

6. Riviere gives the results of tuberculin treatment of tuberculosis in children. He divides these cases into two groups: strictly localized tuberculosis, and tuberculosis not strictly localized, that is, accompanied by symptoms of general disturbance. The success or non-success of tuberculin treatment resolves itself into a question of doses. He believes that many disappointing results are to be accounted for by overdosage. He now considers 1-12000 to 1-8000 mgm. suitable for a child of one year, 1-4000 for a child of five years, and 1-3000 for children of ten to twelve years. The effect on the opsonic index

should be carefully watched, and, a convenient dose being fixed, it is best given every two weeks. He considers it very important to watch the opsonic index as a guide to treatment. In cases where this is impossible, clinical evidence may take its place. For localized tuberculosis he has found tuberculin in suitable doses an almost certain remedy. The improvement is threefold, consisting in a change in the general health, a marked mental improvement and a tendency to local healing. Among his cases of this class he has treated tuberculous dactylitis, superficial abscess, tuberculous glands and tuberculous joint diseases. Tuberculous glands do well, but in prolonged treatment his experience with joint cases has been too short and scanty to give conclusions. Cases of tuberculosis accompanied by symptoms, such as phthisis and tuberculous peritonitis, are certainly benefited by tuberculin in most instances. He urges a wider use of tuberculin in the treatment of tuberculosis in children and believes that poor results are generally due to faulty administration.

7. Osler recognizes two groups of cases of acute pancreatitis, a first in which there is enlargement of the gland, often with hemorrhage; a second in which the gland is in a state of suppuration or necrosis. There are three main causes of acute pancreatitis: (1) mechanical, as a calculus leading to bacterial infection; (2) chemical, as bile, gastric juice or duodenal contents entering the pancreatic duct; (3) most important of all, an infective cause. There were gallstones in nearly one half of his cases of acute pancreatitis. Diagnosis is often impossible. The history is of the greatest importance, especially one of alcoholism in middle-aged men, or a record of gallstones, and then sudden severe symptoms. Ninety per cent of his cases not operated on died, and of those operated upon more than 50% recovered.

8. Northrup gives an interesting description of the open-air roof ward on the Presbyterian Hospital in New York City. He discusses its construction and appointments and its functions and gives his general impression of its usefulness after experience. It is to be hoped that this movement will begin a new era in hospital construction. The great thing to be borne in mind in these open-air wards is that the patient must be made comfortable.

2. Arning and Klein, in reporting the results of their work in the examination of patients in the Hamburg Hospital for venereal diseases, say that they have convinced themselves that the spirocheta pallida is the cause of syphilis, and is pathognomic for the disease when discovered in suspected lesions. The search for this organism should be made a routine measure in hospital work. The authors found the most satisfactory staining method that of Giemsa as modified by Preiss. One hundred and forty cases of clinical chancres were examined, 112 of these being of the male genitals. In only four instances were the spirochetes not found, the reason in two of the cases being that the ulcers had already undergone prolonged local treatment with mercury. In 14 primary lesions of the female genitals the spirochetes were found every time. Only ten failures are reported in 179 cases of syphilitic plaques and patches of various sorts. Seventeen cases of actual or suspected congenital syphilis were examined, and in every instance in which clinical syphilis existed the spirochetes were found. In 32 cases in which the diagnosis was clinically uncertain, the spirochetes were found seven times, and the subsequent clinical course was that of syphilis. Eighteen cases gave a negative result and were treated as soft chancres, but in two of these the occurrence of secondary symptoms showed that the search for spirochetes had not been sufficiently prolonged. In the remaining 7 cases treatment by mercury had already been given, and no spirochetes were found. In 93 cases the clinical picture was that of soft chancre and the examination was made as a species of control; in two of these the spirocheta was found, but the others, in which a very careful search failed to detect the micro-organism, ran the course of a non-syphilitic affection.

3. Boellke thinks he was able, by specific inoculation, to raise the opsonic index in fourteen pneumonias and one empyema. The latter showed pneumococci and streptococci in the aspirated pus. Six days after the first inoculation there were no bacteria in the aspirated pus, and patient was well by the twelfth day; aspiration was the only surgical procedure.

5. Hesse warns against the use of spinal anesthesia unless general anesthesia is decidedly contra-indicated, and says it should never be used for operations above the umbilicus. In his experience of 60 cases he encountered one collapse from the introduction of the needle, annoying symptoms in 7. One case had intense pain in the right arm and headache, the pain spreading to the intercostal spaces; two months after the pain and other sensory disturbances, with exaggerated reflexes, persisted unchanged. He employed tropacocain 0.05. gm., diluted in all cases with 5 cc. of the patients' cerebrospinal fluid.

7. Turan describes the manner in which he has successfully applied Bier's congestion treatment in chronic catarrhal endometritis. He uses a fenestrated intra-uterine catheter, having on its stem a projecting shoulder to keep it from entering too far. The catheter is connected by rubber tubing to a Y-shaped coupling, by means of which it communicates with a mercury manometer and with a suction syringe. A packing of gauze about the shoulder of the catheter prevents the entrance of air into the uterus. Suction is applied by means of the syringe, and negative pressure maintained for a period of from twenty minutes to an hour by clamping the rubber tube. Experience has shown that very little leakage takes place even though the patient walks about during the application. The most suitable pressure has been found to be between 20 and 30 mm. of mercury. The treatment is painless and should be repeated every day for fifteen to twenty-nine sessions. In old chronic cases the results were eminently satisfactory, but recent or acute inflammation contra-indicates this treatment. [L. G. M.]

3. Jahrmärker describes 2 cases, one in a man of sixty-three, the other in a woman of sixty, both of whom rather suddenly developed symptoms of senile dementia accompanied by slowly increasing paralysis of the limbs and face muscles, in the first hemiplegic, in the second paraplegic. The paralyses were accompanied by premonitory symptoms (local spasms, tremors, etc.). This

condition slowly merged into one of complete paralysis and unconsciousness, followed by death. In both cases a diagnosis of pachymeningitis interna hemorrhagica was made, because of the lack of history of trauma, the general marked arteriosclerosis, the slowness of the march of symptoms, and the paralyses combined with symptoms of cortical irritation. The autopsies supported the diagnoses. In the first case (*i. e.*, hemiplegic) there was a one-sided hemorrhagic pachymeningitis. In the second case the process extended over the whole surface of both hemispheres. [R. D.]

4. Maas, O. *Multiple Tumors of the Central Nervous System.*
5. *Ruhemann, J. *The Epidemic Importance of the Influenza Bacillus.*

3. Engel and Bauer observed a series of 48 infants who had received tuberculin injections. In 6 cases, which were tuberculous, the Pirquet reaction was present (*i. e.*, a papule at the point of injection); in 5 cases without demonstrable tuberculosis the reaction was also positive. Out of a series of 280 children of more advanced years, all those with a clinically evident tuberculosis gave a Pirquet reaction. Thus it appears that the reaction is more reliable in children than in infants. The authors find that in comparison with the ordinary tuberculin test, *i. e.*, a general reaction, this local reaction is not to be depended on.

5. Ruhemann has observed that of late years the bacillus of Pfeiffer is less often found in association with clinical influenza. He attributes this to the fact that many people have acquired a partial immunity to the bacillus by repeated attacks of influenza. Also he claims that since the first great epidemics, there has been a constant diminution in the virulence of the organism. [R. D.]

1. Geigel discusses in this paper the physical explanation of the metallic sounds produced in percussion, and the various theories which have been advanced to explain this phenomenon in thoracic percussion. He believes it is due to a discontinuous vibration of an elastic body, which produces high overtones, considerably above the fundamental tone. This condition is present in an air-containing cavity with a tense wall, which can be put in vibration at some point.

2. In most cases of hysteria, the patellar reflexes are increased. An exception to this rule is the case published here by Köster, in which there was a temporary absence of these reflexes. Other cases have been reported, and these are discussed by the author. Most of these are undoubtedly cases of hysteria, and the absence of the knee jerks cannot be attributed to organic lesion of the spinal cord. It is much more common to have these reflexes absent in organic diseases, but the diagnosis of organic disease is not justified merely on the absence of knee jerks. Köster discusses the probable explanation of the absent reflexes, but arrives at no very satisfactory explanation of the phenomenon. In most of the cases in which this combination has existed, there has been muscle weakness, but the lack of muscular tone is not sufficient to explain the absent knee jerks, since in other conditions with marked loss of muscle tone the knee jerks may remain very active, and even in hysterical cases with the same symptoms (astasia-abasia) as the one reported by the author, the knee jerks are more often present.

3. The "nodular lung" is a term used by Uffenheimer to describe certain small nodules resembling miliary tubercles in the lungs of guinea pigs which have been inoculated with various organic substances. These nodules do not have the histological structure of tubercles, and inoculation of them into animals does not produce tuberculosis. They appear to be an excessive development of lymphoid nodules, with which is associated a considerable local eosinophilia in many cases. The interest in these nodules is in the belief of the author that their formation is associated with, or is an expression of some acquired immunity; in this particular case an immunity to tubercle bacilli, since in his cases they were produced by the injection of blood and glands from guinea pigs, recently inoculated with tubercle bacilli. Definite proof of this theory cannot be given, but the presence of the nodules seems to be associated with a resistance to tuberculosis.

4. Klieneberger has made an extensive study of the agglutinins for colon bacilli, which are present in normal serum, and the serum of people suffering from various infections with colon bacilli. Under normal conditions one finds somewhat high agglutination values for colon bacilli, and different strains of bacilli are differently agglutinated by the serum of the same individual. Serum from cases with colon bacilli infection very frequently agglutinates the infecting strain of bacteria, but not always, and the highest agglutination values occur in the serum of cases with fever associated with the infection. The determination of a colon bacillus infection by means of the agglutination test must always be controlled by comparative test with a normal serum, and even under these conditions no very definite conclusions can be drawn from strongly positive reactions; consequently the agglutination of colon bacilli with serum of patients is of comparatively little value to the clinician.

5. This is a report of a single case with autopsy of a quite rare condition. The authors have collected 37 similar cases, and attempt to construct a diagnostic symptomatology. The most characteristic features of it are pain in the right upper quadrant of the abdomen, associated with icterus, hemorrhage into the digestive tract and palpable tumor unassociated with liver-edge or stomach. Diagnosis under these conditions, however, would hardly be possible except when there is associated pulsation of the tumor, and a systolic murmur over it. Even under these conditions it is not likely that the condition will often be diagnosed.

6. The veterinarians have long recognized that food in the stomach of animals was not evenly mixed but was arranged more or less definitely in layers. Prym here shows that the same is true in dogs for a liquid meal of thin consistence. In man the same condition is suggested by the finding of a different degree of acidity in two portions of stomach content removed simultaneously by means of a two-way tube with openings at different levels. This being the case there is much chance for variable results from the analysis of stomach contents after the usual test meals depending on the portion removed. This is true for the Ewald-Boas and the Sahli test meals, and there is even more chance for error in the Mathieu method of determining the total residue. These facts render the finding of minor variations in analyses of stomach contents as of doubtful value in diagnosis, and emphasize the great care that should be exercised in drawing conclusions from the results of various methods of gastric analysis.

7. Türk gives a very full account of an almost unique case. There is a careful description of the cultural characteristics of the yeast isolated from the case.

8. Porges and Pribram contribute a study of two cases of orthostatic albuminuria in which they tested the influence of posture ingestion of food, drugs affecting the general circulation (digitalis, strychnine, chloralhydrate) and those acting on the renal vessels (caffein, diuretin), cathartics, etc., on the excretion of albumin. As a result of these studies they conclude that the condition is the result of local disturbances of the renal circulation, probably following an arterial spasm that obstructs the circulation through the kidneys.

12. By means of ingested bismuth and the orthodiagraph, Groedel has made extensive studies of the position and shape of the full stomach. In the first place this is dependent on the position of the body. In the standing position the more usual shape is that of a siphon, while lying down we have a sandal form. The stomach rotates in change of body posture, on an axis running from pylorus to cardia. Many variations in form and position occur, depending on the shape of the body, abdominal contents, the relaxation of the abdominal wall and the position and degree of filling of the intestine.

[H. A. C.]

Miscellany.

THE AMERICAN NATIONAL RED CROSS.

WE have received from Surgeon-General O'Reilly of the United States Army, the following communication with the accompanying resolutions.

As a member of the Executive Committee of the American National Red Cross, I have been requested to forward to you the enclosed resolutions with the hope that you may find it expedient to kindly print them in your publication and lend what assistance you can in discharging the international duty assumed by this country in agreement with all the great powers, of protecting the Red Cross name and insignia from any use save that agreed upon by the Treaty of Geneva.

In cases where the name and insignia are used as trademarks, the suggestion would be of value that their use should be gradually eliminated within the next three or four years, in conformity with the provisions of the treaty that the prohibition of the use of the emblem and name should be enforced not later than five years after the treaty went into effect.

RESOLUTIONS ADOPTED BY THE EXECUTIVE COMMITTEE, OCT. 18, 1907.

Whereas, by international agreement in the Treaty of Geneva, 1864, and the revised Treaty of Geneva, 1906, "the emblem of the Red Cross on a white ground and the words Red Cross or Geneva Cross" were adopted to designate the *personnel* protected by this Convention, and

Whereas, the Treaty further provides (Article 23) that "the emblem of the Red Cross on a white ground and the words Red Cross or Geneva Cross can only be used whether in time of peace or war, to protect or designate sanitary formations and establishments, the *personnel* and material protected by this Convention," and

Whereas, the American National Red Cross comes under the regulations of this treaty according to Article 10, "volunteer aid societies, duly recognized and authorized by their respective governments," such recognition and authority having been conferred upon the American National Red Cross in the charter granted by Congress, Jan. 5, 1905, Sect. 2, "The corporation hereby created is designated as the organization which is authorized to act in matters of relief under said treaty," and, furthermore,

Whereas, in the Revised Treaty of Geneva, 1906, in Article 27, it is provided that "the signatory powers whose legislation should not now be adequate, engage to take or recommend to their legislatures such measures as may be necessary to prevent the use by private persons or by societies other than those upon which this convention confers the right thereto of the emblem or name of the Red Cross or Geneva Cross."

Be it resolved, That the Executive Committee of the American National Red Cross requests that all hospitals, health departments and like institutions kindly desist from the use of the Red Cross created for the special purpose mentioned above, and suggests that for it should be substituted some other insignia, such as a green St. Andrew's Cross on a white ground, to be named the "Hospital Cross," and used to designate all hospitals (save such as are under the medical departments of the army and navy and the authorized volunteer aid society of the government), all health departments and like institutions, and, further,

Be it resolved, That the Executive Committee of the American National Red Cross likewise requests that all individuals or business firms and corporations who employ the Geneva Red Cross for business purposes kindly desist from such use, gradually withdrawing its employment and substituting some other distinguishing mark.

THE OPERATIVE TREATMENT OF CANCER.

PROF. E. GOLDMANN, of Freiburg, in the course of an address on "Malignant Disease" delivered before a meeting convened by the Surgical Section of the Royal Society of Medicine, held on Oct. 23, commented on the defensive substances manufactured in the human body against malignant tumors. Present knowledge enabled the inference to be made that the body's first line of defence was established on the boundary of an invading growth. That explained those cases in which cancers of slow growth and long duration had been removed with the result that the patients have returned in a short time with recurrences of an alarming nature which have grown rapidly. It appeared to Professor Goldmann that in such cases the surgeon's knife had done harm, for by removing the growth he has destroyed the barrier of defence, which the body has carefully raised up during the long period of the tumor's existence. He thought that the time had come to consider whether stereotyped surgical interference was the only remedy of the future for malignant growths. — *Lancet.*

Correspondence.

LETTER FROM SAN FRANCISCO.

The Plague Situation in San Francisco.

San Francisco, Nov. 12, 1907.

Mr. Editor: I am enclosing you a report to date on the plague situation in San Francisco.

The first authentic case in this epidemic was verified May 27 and no subsequent case was noted until the middle of August when within a few days five or six cases were found in the City and County Hospital. The situation seemed serious because these cases developed in widely scattered parts of the city, but chiefly along the water front in the miserable shanties which an inefficient city government allowed to remain occupied in spite of adequate quarters for the homeless in sanitary and well constructed camps. It is to the filth and lack of sewer connections of these irregular camps that we attribute also our unprecedented epidemic of typhoid fever a year ago.

Up to Nov. 9, 90 verified cases of plague had been reported with 57 deaths.

Our present mayor — a graduate in medicine as well as in law — was keenly alive to the situation, and within a few days of the matter being brought to his attention, he had reorganized the Department of Health from top to bottom and asked the Federal Government for the further help of its Marine-Hospital services. Eight years ago when we had a similar but smaller outbreak, Dr. Rupert Blue was sent to us, and to his efficiency as a sanitarian we owe the thorough cleaning out of the disease. He remained with us until every cellar and underground passage in Chinatown had been cleaned up and cemented, hordes of rats killed, until the disease was no longer found among them and until no new case among human beings had been reported for a year. It was with considerable satisfaction that we heard promptly that Dr. Blue was on his way here again to assume charge of the situation with our local Board of Health. The first epidemic, it it can be called rightly by that name, resulted in about twenty-five people getting the disease, only one of whom was white — the remainder being Japanese or Chinese.

In the present epidemic only one or two Chinamen have been afflicted, the remainder being chiefly the Latin races who are segregated along the water front. It is needless to say that nothing has been left undone to stamp out the disease. The irregular camps have been vacated and destroyed and stables and cellars everywhere have been rigidly overhauled. Rats are being trapped and poisoned by the thousand and it is gratifying to note that fewer and fewer plague-infected rats are being found in proportion to the others. The number of cases and suspects reported is also diminishing, and we hope to have a clean bill of health before long. In the meantime an isolation hospital has been built and surrounded by a corrugated iron fence buried two feet in the ground. Here the clinically diagnosed cases are taken at once. They are cared for by a staff of physicians, and every case receives attention from the resident physician and the representative of the Marine-Hospital Service each day. The nursing is done by a staff from the City Hospital. The Board of Health provides a suitable laboratory where two bacteriologists with a number of medical assistants check up the material brought in for investigation. An incineratory on the ground has been provided for and nothing leaves the enclosure in the way of waste product or sewage.

It might be interesting to the medical profession throughout the country to refer briefly at this time to the need in San Francisco of a school for the study of tropical diseases. It is no uncommon thing for us to have in the wards of our public hospital cases of pernicious malarial fever, tropical liver abscess, leprosy, beri-beri, and countless cases with intestinal parasites. Our relation to the Orient is not an unmixed blessing. It seems high time that more attention was paid to the portal of entry of diseases which are certain from now on to menace us all the time.

The supervisors of the city are of the opinion that the eradication of plague in San Francisco is not merely a local matter and that the Federal Government should assume part of the expense. The city is willing to expend $10,000 a month and proposes to ask the general government for the other $30,000 which are required.

At a conference, attended by the Governor, the Mayor, and various city and state officials, which was held Nov. 8, the following resolutions were adopted:

Whereas, the United States Marine-Hospital Service, acting in conjunction with the state and the city authorities, has thus far successfully coped with the plague situation prevailing in the city; and

Whereas, it is of vital importance that the labors of these joint bodies be continued without interruption; and

Whereas, the city of San Francisco has contributed most of the funds necessary for the accomplishment of the work of these joint bodies; and

Whereas, we believe that the successful prosecution of this work is a matter of concern to the entire United States, and for that reason one that should be controlled by the Federal Government, and that San Francisco cannot, without seriously crippling itself, continue to defray the expenses of such work, by reason of the enormous demands now being made upon its treasury for rehabilitation purposes; now, therefore, be it

Resolved, That it be the sense of this meeting that the chairman of the Finance Committee of the Board of Supervisors of San Francisco, the president of the Board of Health of San Francisco and the secretary of the State Board of Health proceed at once to the city of Washington for the purpose of securing from the Federal Government the necessary financial means for the prosecution of this work to a successful conclusion.

Very truly yours,

Philip King Brown, M.D.

ON THE TREATMENT OF TYPHOID FEVER WITH SPECIFIC SERA, FILTRATES, AND RESIDUES (VAUGHAN).

Boston, Nov. 16, 1907.

Mr. Editor: I was very much interested to read Dr. Prince's letter in the last number of the Journal concerning the unreliability of statistics when applied to anything but a very large series of cases of typhoid fever. I, myself, have always been conscious of this unreliability, though I was not aware that it had been so conclusively demonstrated as is shown by Dr. Prince's investigation of 3,000 cases.

This lack of faith in figures I thought I had made plain when I said

(1) "A comparative study of 130 cases of typhoid fever appears in the following tables, which offer many points of interest, but which *must be scanned very critically lest they convey false impressions.*"

(2) "*Taken with the reserve with which all such tables must be observed.*"

(3) "That specific therapy increases *apparently*."

(4) "This claim [prevention of relapses] is, . . . of course, *subject to confirmation by observation upon a much larger series of cases.*"

(5) "The nontoxic residue *seems* to make the typhoid process longer but milder."

It is apparent, therefore, that, if eight years are consumed in the investigation of 130 cases of typhoid fever, it is scarcely possible within a single lifetime to make a satisfactory statistical study of treatment in typhoid fever. I do believe, however, that one who has spent ten years in studying typhoid fever from various points of view is entitled to have some very strong impressions and beliefs, and I should like to state again my *belief:*

(1) That typhoid fever can be favorably influenced by specific methods of treatment, if that treatment can be instituted early enough. Lack of a positive diagnosis is often a great hindrance, but the newer methods of blood culture promise better results in this regard.

(2) That by specific treatment the relapse in typhoid fever can be largely eliminated.

Very truly yours,

Mark W. Richardson, M.D.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING NOV. 16, 1907.

E. Z. DERR, medical director. Detached from the navy yard, Portsmouth, N. H., and ordered to the naval recruiting station, Providence, R. I.

J. M. STEELE, medical inspector. Detached from the naval recruiting station, Cleveland, Ohio, and ordered to the navy yard, Portsmouth, N. H., and to additional duty in command of the naval hospital at that yard.

V. C. B. MEANS, surgeon. Sick leave extended three months from Nov. 16.

J. D. MANCHESTER, passed assistant surgeon. Detached from the naval hospital, Pensacola, Fla., and ordered to the "Panther" when commissioned.

J. H. PAYNE, Jr., passed assistant surgeon. Detached from the naval recruiting station, Providence, R. I., and ordered to the naval recruiting station, Cleveland, Ohio.

R. B. WILLIAMS, passed assistant surgeon. Detached from the "Maine" and ordered to the "Franklin."

R. A. WARNER, assistant surgeon. Detached from the "Louisiana" and ordered to the naval hospital, Pensacola, Fla.

L. H. WHEELER, assistant surgeon. Ordered to the naval recruiting station, Indianapolis, Ind.

D. H. CASTO, assistant. Detached from the naval recruiting station, Indianapolis, Ind., and ordered to the "Maine."

W. G. STEADMAN, JR., assistant. Detached from the "Franklin" and ordered to the "Louisiana."

G. H. BARBER, surgeon. Detached from the "Kearsarge" and ordered to the "Wabash."

H. D. WILSON, surgeon. Ordered to the "Kearsarge" Dec. 1.

M. W. BAKER, passed assistant surgeon. Detached from duty at the naval hospital, New Fort Lyon, Colo., and ordered to the naval hospital, New York, N. Y., for treatment.

L. W. BISHOP, passed assistant surgeon. Detached from the "Missouri" and ordered to continue treatment at the naval hospital, New York, N. Y.

R. H. NICHOLS, passed assistant surgeon. Detached from the naval recruiting station, Kansas City, Mo., and ordered to the "Missouri."

J. L. BELKNAP, assistant surgeon. Detached from the "Wabash" and ordered to the naval hospital, Boston, Mass.

G. L. WICKES, assistant surgeon. Ordered to the naval recruiting station, Kansas City, Mo.

J. G. FIELD, surgeon. Ordered to the naval training station, San Francisco, Cal.

C. BIDDLE, surgeon. Detached from the naval training station, San Francisco, Cal., and ordered to Washington, D. C., for examination for promotion, and then to wait orders.

C. N. FISKE, passed assistant surgeon. Detached from the "Yorktown" and ordered to the naval hospital, Mare Island, Cal.

G. W. SHEPARD, assistant surgeon. Ordered to the naval hospital, Mare Island, Cal.

R. I. LONGABAUGH, assistant surgeon. Detached from the naval hospital, Mare Island, Cal., and ordered to the "Yorktown."

C. A. LUNG, surgeon. Ordered to the naval recruiting station, Philadelphia, Pa.

L. W. BISHOP, passed assistant surgeon. When discharged from treatment at the naval hospital, New York, N. Y., ordered to the naval training station, Newport, R. I.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — The regular meeting of the society will be held in Sprague Hall, Medical Library Building, on Monday, Nov. 25, 1907, at 8.15 P.M. Program: Personal Experience with Specific Vaccines in the Treatment of Bacterial Disease: Dr. Mark W. Richardson. The Value of Vaccine Therapy in the Treatment of Bacterial Disease: Dr. Cleaveland Floyd (by invitation). Discussion: Drs. H. F. Hartwell and Roger Lee.

DANIEL FISKE JONES, M.D.,
Secretary.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY IN CONJUNCTION WITH THE BOSTON MEDICAL LIBRARY. — Meeting Wednesday, Nov. 27, 1907, at 8.15 P.M., John Ware Hall. Some Observations upon Renal Surgery, from an Analysis of One Hundred and Thirty-five Operative Cases: Dr. G. E. Brewer, New York. An Insidious Type of Nontuberculous Pyelonephritis: Dr. A. L. Chute. Light refreshments after meeting.

J. C. MUNRO, M.D., *Chairman.* J. C. HUBBARD, M.D., *Secretary.*

THE NORFOLK DISTRICT MEDICAL SOCIETY.—A meeting for Scientific Improvement will be held at Masonic Temple, 171 Warren Street, Roxbury, on Tuesday evening, Nov. 26, 1907, at 8 o'clock. The following papers will be presented: Cough in Relation to Nose and Throat Affections: Dr. C. D. Knowlton. A Plea for a More Accurate Diagnosis in Throat and Nose Diseases by the General Practitioner: Dr. H. V. McLaughlin. Vasomotor Disturbances (Deviations of Septum; Hay Fever): Dr. F. D. Lyon. The Tonsils and Their Relation to General Infection: Dr. C. P. Sylvester. The discussion will be opened by Drs. J. B. Brainerd, C. R. C. Borden and A. E. Rogers.

WILLIAM H. ROBEY, JR.,
Secretary.

RECENT DEATHS.

WILLIAM FREDERICK HEALD, M.D., M.M.S.S., died in Pepperell, Nov. 6, 1907, aged sixty-four years.

DR. THOMAS H. HOLGATE, an old-time practitioner of New York, died on Nov. 14 at his home on West 14th Street, where he had resided for many years. He was graduated from Bellevue Hospital Medical College in 1869, and was seventy-six years of age.

BOOKS AND PAMPHLETS RECEIVED.

The Treatment of Fractures. With Notes upon a Few Common Dislocations. By Charles Locke Scudder, M.D. Sixth edition, thoroughly revised and enlarged. Illustrated. Philadelphia and London: W. B. Saunders Company. 1907.

Papers upon Genito-Urinary Surgery. By A. T. Cabot, A.M., M.D. Reprint.

The Medical Record Visiting List or Physicians' Diary for 1908. New revised edition. New York: William Wood & Co.

Transactions of the Twenty-ninth Annual Meeting of the American Laryngological Association held at Washington, D. C., May 7, 8 and 9, 1907.

Textbook of Organic Chemistry for Medical Students. By Dr. G. v. Bunge. Translated with additions by R. H. Aders Plimmer, D.Sc. (Lond.). London, New York, Bombay and Calcutta: Longmans, Green & Co. 1907.

Original Articles.

ANTERIOR POLIOMYELITIS IN THE ADULT, WITH ILLUSTRATIVE CASES.

BY G. L. WALTON, M.D., BOSTON.

This disease deserves more notice on the part of the general medical profession. In the first place, it is of not infrequent occurrence. I have notes of ten typical cases seen in consultation during the past four years. In the second place, its early recognition is important as bearing both on prognosis and treatment, or rather care, for too energetic treatment in the early stages is in danger of retarding rather than favoring the ultimate progress.

The clinical history of these cases conforms much more accurately to the textbook type than do cases of certain other disorders with which the general practitioner is more familiar.

Symptoms of poliomyelitis in the adult are overlooked, not because they vary materially from the same disease in infancy (infantile paralysis) but because this diagnosis does not enter the mind of the practitioner in case the patient is an adult, whereas it is ever present when the patient is a child.

In the adult appears the same stage of fever, during which signs of irritation appear, and during which the destruction of anterior spinal gray matter produces relaxed paralysis of various muscle groups, without loss of sensation or sphincter control (temporary loss of sphincter control did occur, however, in the first case reported); there are the same favorable prognosis as regards health and the same gradual disappearance of paralysis with more or less permanent residue.

The essential features point, in the adult as in the infant, to an infectious process, of more or less diffuse onset, but having for its chief point of attack the anterior gray matter of the cord, to which region the ultimate injury is limited.

It is not improbable that the original infection involves, to some extent, the meninges, and even the nerve sheaths, as shown by rigidity and sometimes retraction of the neck, pain in the back, neck and extremities, and general tenderness. These symptoms attract little attention in the child, and may even be accompanied by convulsions, without diverting attention from the important feature, namely, absolute flaccid motor paralysis of rapid onset unaccompanied by anesthesia. It is this combination which points distinctly to disease of the gray matter of the cord rather than to the meninges or the peripheral nerves.

In the adult the initial symptoms are apt so to color the picture that the essential nature of the injury is overlooked, and the final paralysis is erroneously attributed to the remains of meningitis or neuritis. The following notes are those of two recent cases in which the initial symptoms indicated that the meninges shared in the original infection.

Case I. C. D., male, sixteen, patient of Dr. Beaton, of Franklin Falls, N. H. Previously well and strong. On first day walked two and one-half miles; felt as if had "taken cold"; could not walk home. On second day, feverish; on third day, consulted physician; temperature 104° F., *pain in back of neck with marked retraction of head;* headache; heavy feeling in limbs without numbness; on fourth day, pains in arms; temperature 105° F.; on the fifth day and for two days after required catheterization; on sixth day temperature 102° F.; relaxed paralysis of both legs and right arm; patient feels well, and stiffness of neck has practically disappeared; on seventh day, temperature 100° F., no further extension of paralysis; on tenth day, temperature was normal and patient began sitting up, after which pain and tenderness reappeared in the legs and forced his return to bed, since which they have lessened. Within a month after the onset the arm had nearly recovered its power, but both lower limbs were practically helpless with loss of all reflexes.

It is too soon to announce the final result of this case, but indications point to incomplete recovery as regards the paralysis. In this case the attending physician blamed premature effort for the return of pain and tenderness, an opinion with which I am inclined to coincide. There was certainly no fever or other indication of recurring infection, an extremely rare complication in any event.

Case II. G. G., male, twenty, patient of Dr. May, of Newton. Previously well and strong. On first day was in bed complaining of headache and *sensitiveness to light;* temperature 102° F.; the third day was up but easily tired; on fourth and fifth days, patient kept quiet without definite symptoms; on sixth day, chills and malaise, vomiting, temperature 102.5° F., *general hyperesthesia,* blood count 14,000 whites. On seventh day, temperature 101.4° F., listless, sleepless, *severe pain in head and back, inability to bear light* and sudden onset of complete relaxed paralysis of left shoulder group without anesthesia; *marked rigidity of neck and of back;* on eighth day, while the temperature was still elevated, the paralysis spread to the other arm and to both legs; on ninth day, stiffness and pain had practically disappeared and temperature was normal, general condition was good, but paralysis was complete.

The forecast for the future is the same in this as in the preceding case.

In four other of the ten cases stiffness and pain in the neck were prominent symptoms at the onset, namely, cases 4, 5, 8 and 10.

The distribution of the paralysis in these cases renders it probable that the meningeal infection was coincident with, rather than in extension of, the cord lesion which caused the final paralysis. In Case II, for example, the stiffness, pain and retraction were marked in the *neck,* whereas the final paralysis involved the *lower limbs* almost exclusively.

Although it seems that poliomyelitis in the adult conforms in many ways to the ordinary poliomyelitis of infancy, its clinical features may diverge sufficiently to render the diagnosis far less easy, especially if the practitioner is not on the lookout for it. The apparent difference is, perhaps, largely due to the ability of the adult more

accurately to describe his symptoms, partly also to the more leisurely onset of the disorder.

All the cases coming under my observation have occurred in young robust adults, generally from seventeen to twenty, eight of them males.

The affection has been ushered in by severe headache and neckache, perhaps backache, general malaise, with or without chills, sometimes with general pain and tenderness, sometimes with marked rigidity of the neck and retraction. The symptoms of an ordinary "cold" have been common at the onset of, or perhaps preceding, the infection of the nervous system, doubtless indicating the initial action of the micro-organism. The fever has run a fairly moderate course; it has sometimes, but not generally, reached 104° F., and has lasted rather longer than is common in children, for example, seven days. The paralysis is longer deferred than in children, but when it appears it may do so with great rapidity, perhaps in the course of a few hours, but it is generally longer appearing than in infants. In the following cases the paralysis appeared on respectively the ninth and sixth days.

CASE III. C. H., male, seventeen. Patient of Dr. Hunt, of Newtonville.

Athletic boy. First day, legs felt tired and painful. The next day, was walking about. The third day, nausea, malaise and headache. The fourth day, there was fever, temperature 101.6° F.; was in bed. Had pain in back, head and legs. The fifth day temperature 100.4° F.; pain continued. The sixth day the temperature was 102° F.; ached all over, including arms. The seventh day the temperature was 100° F.; legs ached. The eighth day the temperature was 99.8° F. in the morning, 100.7° F. in the afternoon; vomited; pain lessened. The ninth day the temperature was 99° F. This day appeared definite loss of power, and patient had to be helped to chair. The tenth day he handled the legs better and felt better. On the eleventh day the temperature was normal; there was no numbness or sphincter disturbance. Moderate tenderness in both arms and in left leg: cannot raise left knee in bed nor roll left leg. All affected muscles react to faradism. Knee jerks active right, absent left. No anesthesia.

Three months later was up and about, swinging the left leg slightly but able to walk without a cane. Can go up stairs one step at a time. (No extension of paralysis after temperature normal. Case of practical recovery.)

Went on crutches about eight months, then with cane. About eight months later left off cane and from that time has had practical use of leg except a little difficulty in ascending hills and running.

CASE IV. D. D., female, seventeen. Seen recently in consultation with Dr. Adams, of Pittsfield, and Dr. Powers, of Boston.

Well and strong. First day, chilly and severe headache. Second and third days, dull ache in arms, legs, and especially neck and left shoulder. Fourth day the pain continued. Temperature, 99° F. to 100.2° F. Sixth day, knees gave out, especially the right; temperature was normal. No loss of sensation; no sphincter disturbance. Loss of power to raise right foot at ankle, and to less degree same loss on left. Loss of power in left shoulder and upper arm group, especially deltoid and biceps. Weakness in extension of left wrist. Movements of hands and toes normal. Marked stiffness of neck and inability to bend head forward, actively or passively. No further extension of paralysis. Two weeks later all muscles contract voluntarily and to faradism except tibialis anticus on the right.

The paralysis may rapidly spread in the course of a day or two, but *in only one* (Case 5) *of the 10 cases reported was there further extension of paralysis after the fever had disappeared.* This may be of importance in prognosis, but further data are desirable. At present I am inclined to prophesy that there will be no further extension of paralysis after the temperature has dropped to normal, whereas in case it has not done so the family should be warned of the possibility of extension.

In Case II the left shoulder group alone had become paralyzed on the seventh day; the temperature was still somewhat elevated. The next day all four extremities were completely helpless. In Case IV, on the other hand, which I saw on the seventh day after the temperature had become normal, the paralysis had come to a standstill and was practically limited to the left shoulder group, the flexor group of the right leg, and to a less degree of the left leg. The prediction of no further extension was verified by the further history.

It is justifiable to give a good prognosis as regards life, even though there may be at the onset more or less meningeal accompaniment, and though the paralysis may not have reached its maximum. With regard to disappearance of paralysis, the prospect seems to me better than in children. A proportion of four practical recoveries in ten cases is surely unprecedented in the history of infantile paralysis.

A brief history follows of the cases in which, as in Case III, practical recovery followed.

CASE V. P. O. D., male, twenty-seven years. Patient of Dr. Mead, of Winchester.

Robust. In the evening of first day noticed weakness of fingers in undressing; the next day difficulty in walking, and toe-drop. Third day the legs were more helpless but he could still stand. Fourth day was worse, but went to his office, having to be helped to the train. Fifth day could not rise from chair but could walk across room. Sixth day could not even sit up in bed; dull ache in back of neck, no numbness or trouble with sphincters. There had been no elevation of temperature since the third day (that is, there was in this case extension of paralysis after temperature became normal).

Physical examination shows paralysis, purely motor, especially affecting extensors of both lower extremities. Gradual improvement set in about a month after onset, and three months later he could skate, dance and ride without trouble. Detailed examination showed all movements perfect except a slight difficulty in using the arms, as in putting on the coat.

CASE VI. R. D., male, nineteen. Patient of Dr. Beaton, of Franklin Falls, N. H.

First day, fever 102° F. Second day, pain in back, Third day, paresis of superior oculi recti; pupils large and immobile to light; pain in left shoulder and in back. Fourth day, was unable to walk a crack and left toe dragged; knee jerk was absent. Fifth day, the paralysis increased, temperature became normal on this day. Six weeks later, practical recovery, but slight weakness in arms on use, as after a long drive.

CASE VII. Male, fifteen. R. C. T. Patient of Dr. Jackson, of Milford.

Previously well, though not strong. At onset fever during seven days (highest temperature 103° F.). In bed four weeks. No pain in head or back; no soreness,

but pain in both legs. No sphincter trouble, no numbness. Before fever subsided found could not move leg. Improved gradually. When I saw him (six months later) left calf nearly one and one-half inches smaller than right, left thigh two and one-fourth inches smaller than right. Coldness of left foot. Complete and extensive relaxed paralysis. The leg is now (three years later) used practically as well as ever.

In the following case the boy now (three years later) gets about as well as ever, but still has weakness in the leg.

Case VIII. P. A., male, seventeen. Patient of Dr. Stevens, of Belmont.

Previously well and strong. At onset thought had taken cold; sore throat, temperature of 103° F. One week later similar attack accompanied by backache and temperature of 103° F. Pain also in back of neck, and stiff neck. In bed ten days during which lost power in left leg, with toe-drop; knee jerk absent left, lessened right. Improvement gradual. Six weeks later could not stand on toes. Three months after could stand on toes but not on heels. Six weeks later could not bend his back to lace his shoes, but after another six weeks could do so. Three months after onset left calf measured three-fourths inch less than right; left thigh just above knee one inch less than right. Three months later complete paralysis of tibialis anticus and peroneus longus persisted on the left, with degeneration reaction.

In the two remaining cases improvement has come to a standstill for so long a time as practically to preclude recovery.

Case IX. M. A., male, twelve. Patient of Dr. Bowker, of Brookline.

Active and strong. Had a "cold" and did not feel well during few days prior to day of actual onset. First day, headache and was delirious after rough usage at football. Second day, temperature 102.5° F., headache, soreness in chest and back. Third day, still in bed. Fourth day, up. Fifth day, temperature normal; this day appeared loss of power in right leg. No loss of sensation, but marked loss of power of thigh muscles right, less left; knee jerks absent both; some loss of power in right leg also. Improvement appeared two days later, but paralysis of leg has persisted four years, and mechanical support is necessary.

Case X. M. C., female, thirteen. Patient of Dr. Averill, of Campello.

Robust. Played football up to day of onset. That night had pain between shoulders. The next day rode bicycle. Coming home found difficulty in getting on and off and in pushing. (Has had coryza two days.) The second day knees gave out, then arms. The third day could only crawl on knees; marked tendency to retraction of head; temperature, 104° F. Temperature normal from the seventh day. The ninth day still unable to bend head forward. No extension after temperature became normal. The paralysis has remained stationary for three years. Patient is unable to walk.

I cannot forbear emphasizing the importance of rest in the treatment. The patient cannot be kept too long in bed, nor too long postpone bearing the weight upon the paralyzed limbs. It is of importance already, while the patient is in bed, to commence upon treatment directed toward the obviation of contractures. A light elastic stretched from the foot to the knee[1] is useful in toe-drop, as well as a cradle to keep off the weight of the clothes. Energetic massage and electrical treatment should be postponed at least a month, after which they contribute greatly to favorable progress. Otherwise the management of the case is orthopedic.

Conclusions. — Acute or subacute poliomyelitis in young adults is not rare.

The real seat of the infection is apt to be obscured by temporary symptoms pointing to the meninges and nerve sheaths. The implication of the meninges is probably independent, not an extension from the substance of the cord.

The onset of paralysis is more retarded in adults than in infants, and the extension of paralysis from one group to the other is less immediate.

No extension of paralysis is to be expected after fever has subsided.

Prolonged rest of the affected muscles is desirable, as well as early orthopedic measures.

DIAGNOSIS OF GASTRIC CANCER.*

BY RICHARD F. CHASE, M.D., BOSTON.

Cancer of the stomach is a very common disease, more common than many realize. It causes about 2% of the total mortality. Of all cancers, nearly 50% involve the stomach. Statistics show that the disease is on the increase. In the writer's experience gastric cancer is encountered once in about every one hundred and fifty patients over fifteen years of age, as seen in a general medical clinic. If in such a clinic we should exclude the considerable number of patients under thirty years of age, we would then find the per cent of cancer patients vastly increased. Of a recent series of 100 consecutive cases of gastro-intestinal diseases taken from private records, it was found that 10 or 10% were cancer of the stomach.

The general physician who sees but one or two of these cases yearly rarely has the great seriousness of the subject brought home to him, as does the physician or surgeon who encounters fifty to one hundred or more cases each year. Yet it is upon the general physician that the welfare of these patients most depends, for it is he who first sees them and first directs their treatment.

Since there is no medical cure for the disease, and because surgery if taken advantage of early enough may bring about cures, an early diagnosis and resort to surgery is the accepted course to be taken.

But here the very important questions arise, By what means and how early may the diagnosis be made?

Medical means of diagnosis:

History. — The symptoms arising from gastric cancer are usually of short duration at the time the patient first seeks treatment; rarely have

[1] An admirable appliance for distributing the pull of the elastic is the boot of Gowers, made of a single piece of sole leather, cut so as to make a hinge at the heel.

* Read at the meeting of the Middlesex North District Medical Society, Jan. 30, 1907.

they extended over a period of more than three to six months. Yet how often cancer has been excluded in the diagnosis, when present, because the patient may have had gastric symptoms for several years! In such cases of cancer, careful inquiry will almost always reveal the fact that the *character* of the symptoms or the *symptoms* themselves have recently changed. That is, the symptoms of a chronic "dyspepsia" have given place to those arising from cancer. Information regarding past ulcer should always be sought, because recent findings show that about 50% (some say 80% to 90%!) of cancer patients give a history of former ulcer.

Age. — It is well known that the disease occurs most often between the ages of forty and seventy years, but cases occurring between the ages of thirty and forty years are by no means rare. In one of the writer's recent cancer patients, the disease occurred at the very early age of twenty-five years, eleven months. This case will warrant a further report.

Weight. — It is equally well known that loss of weight is a very constant symptom. Just how constant and progressive, and of what diagnostic value this symptom is, will be shown in a measure by further reference to the 10 cases already mentioned.

In 8 of the cases at the time of their first visit there were losses of weight from 3½ to 46 lb.; in the other 2 cases there was extreme emaciation. But of *far greater* diagnostic value is the progress of weight during observation and modern medical treatment. Of the 10 cases, 6 were observed and treated from four to fifty-two days, as may be noted in table. Each case during treatment, regardless of the great alleviation of symptoms in some cases, the increased diet and improved digestion, showed a loss of weight.

Occasionally, frequently perhaps, a maintenance or even slight increase in weight may be temporarily observed. But in gastric cancer this condition can be of but brief duration. Considerable alleviation of symptoms and increase of weight in the first ten days of treatment should not lead the physician to too early abandonment of the diagnosis of cancer. Since a progressive loss of weight is rarely encountered during the treatment of gastric disorders other than cancer, its observation is strongly suggestive of a malignant condition.

By observing a patient's weight is meant the weighing of a patient at each visit on a set of accurate scales, due allowance being made for changes in clothing and other conditions influencing the weight. Of course more accurate information might be obtained by weighing the patient stripped, but this method has been found both impractical and unnecessary in office work.

The weight of patients with gastric stasis should always be taken preferably after the stomach has been evacuated, and only such weights are to be compared.

The reason for this is that in cases of stasis, the contents of the fasting stomach may weigh from one to several pounds, hence after evacuation of the stomach, the patient weighs from one to several pounds less, depending, of course, on the amount of fasting contents. Not infrequently loss of weight has been the chief factor in determining the probable presence of cancer; at other times, its continued absence has been the chief sign by which that disease was excluded. Let there be a more general use of this accurate diagnostic instrument, the weighing scales; then will cancer of the stomach be suspected at a much earlier stage of the disease, than at the present time.

If from the history, age and loss of weight (enough points in any case to arouse suspicion) we suspect cancer, then by a thorough physical examination, together with the application of the various diagnostic tests at our command, we can soon strengthen or confirm our suspicions in the case of cancer, or prove their falsity in case of the existence of another condition.

Chemical tests. — The continued absence of HCl and the *persistent presence* of lactic acid, when frequent gastric lavage is employed, are chemical abnormalities of the gastric juice most often met in cancer of the stomach, and very rarely in other conditions. These changes in the secretion are observed in most of the advanced cases of this disease, although with the lesion located at the cardiac end of the stomach, they may be met at a fairly early stage. On the other hand, usually in cases with the lesion at the pyloric end, the HCl may be present in normal or even in excessive amounts, and as late as the last few weeks of the patient's life, but in these cases gastric stasis is almost always present and has probably existed for some time prior to this late stage.

The finding of food in the fasting stomach, at times when it should be empty, indicates either impaired peristalsis-stasis, or atony, or pyloric obstruction, conditions most often caused by cancer.

In the absence of gross signs of stasis, the finding of microscopic fragments of food in the rinsing water, several hours after the stomach has emptied itself, and especially if the lactic acid bacillus is present, is considered by Ziegler [1] an early and constant symptom of cancer.

Salomon's test. — The detection of appreciable amounts of albumin by Esbach's reagent, in salt solution which has been used to wash out the stomach, several hours after the stomach has emptied itself, according to Kuttner,[2] Zirkelbach [3] and others is a reliable and early sign of cancer. In a limited number of cases, the writer has thus far obtained positive results in cancer cases only, and negative results in mucous gastritis and other nonmalignant diseases. The test seems worthy of further application.

Mechanical and other means. — Very often aspiration of the stomach contents reveals the presence of free blood, and in cases in which hematemesis has never occurred. This finding, together with other symptoms, may suffice to

[1] Ziegler: Zeitschr. für klin. Med., lviii, Nos. 5, 6.
[2] Kuttner: Berl. klin. Wochenschr., xlvii, Nos. 20 and 26.
[3] Zirkelbach: Arch. für Verdauungskrankh., xii, No. 5.

practically confirm the diagnosis. The repeated detection of occult or invisible blood in the feces, if the proper precautions are taken in the tests, is a valuable diagnostic sign, and especially so in cases in which blood has not been otherwise observed.

Inability to pass a stomach tube more than 15 to 16 inches indicates an obstruction at the lower end of the esophagus or at the cardia; this condition with other signs may point strongly to a malignant disease.

Much delay or complete absence of the "deglutition sound" after taking a swallow of water also has the same significance. Simple palpation of the stomach, if skillfully carried out, will at times reveal the presence of very small tumors, even merely indurated areas on the anterior wall. And should doubt exist regarding the presence of a tumor, inflation and palpation may decide the question. Inflation and palpation is also one of the best means of locating certain gastric tumors, and of distinguishing between tumors of the stomach and of other organs.

Since the subjective symptoms of this disease are so closely simulated by those of other gastric disorders, they are of but little diagnostic value. Pain, however, of some variety is a very constant and fairly early symptom; so also is anorexia.

Numerous other tests of more or less value are sometimes employed in the diagnosis of this disease. However, the proper application of *all* the methods of diagnosis here mentioned will enable one to arrive at a reasonable certainty of the presence of gastric cancer, when present, much earlier than the diagnosis was formerly made; and in other nonmalignant cases by the same means, one may exclude cancer in a reasonably short time.

Please remember that it is quite as important to exclude cancer in its absence as it is to make a positive diagnosis when present. The above methods are equally valuable in either case.

And, furthermore, let it be remembered that the medical man's full duty to his suspected cancer patient has not been done until *all* of the medical means of diagnosis, if required, have been applied. The old cardinal symptoms of gastric cancer have been purposely omitted because if we are not to see patients until after the appearance of these symptoms, then there is little need of making a diagnosis.

If there are still some physicians who believe that a positive or negative diagnosis of cancer, as the case may be, can be made, simply by a chemical examination of the gastric juice, then the sooner they relieve themselves of this idea, the better it will be for all concerned.

There should no longer be occasion for the utterance of such laments as the following, recently made by one of our prominent surgeons:[4] "It has been pathetic, in some cases, to have patients withheld from operation by supposed absence of cancer, because of the presence of HCl" (in the gastric juice).

[4] Munro: Transactions, Mass. Med. Soc., 1904.

The value of the laboratory methods of diagnosis has at times been overestimated by physicians, and underestimated by some surgeons. It should be remembered by both physicians and surgeons that of our medical means of diagnosis, the laboratory tests constitute but a *part*. As is well known, most surgeons advocate surgical exploration as the best means of making an early diagnosis of cancer

There may be some surgeons who believe, even as John B. Deaver[5] does, that "no patient who presents symptoms of chronic gastric dyspepsia should be allowed to go on his way without operation, as a preventive of malignant disease." But William J. Mayo,[6] who advocates and is as prompt in carrying out early exploration as are most surgeons, says of the diagnosis of cancer: "The most careful and painstaking methods of examination, including laboratory tests, should be insisted upon, but they should not be unduly prolonged."

It can be most truthfully stated that if Mayo's advice is heeded, there will be much less needless gastric surgery, and far more cancer patients will be forthcoming, at a stage of the disease warranting a greater number of radical operations. But in this work there must be intelligent and prompt co-operation on the part of the general physician, for it is he whom the patient first consults, and it is during these early visits that the true condition must be suspected, and determined by some means within a very short time.

We are now confronted with the highly important question, How much time may be allowed for the carrying out of the medical means of diagnosis? Of course, no rule can be established for all cases, except the general one, that it must be as short as possible. In advanced conditions the diagnosis may often be made with much certainty at the first or second visit. At this time a radical, in fact any, operation is usually out of the question. In selected cases a palliative operation may prove of some benefit. In earlier cases, two or three examinations in as many days or a week's time may be necessary. At this stage of the disease occasionally a condition will be found which warrants a radical operation, or, failing in this, if the lesion is at the pylorus, a gastro-enterostomy may prolong the patient's life several months.

In a still earlier class of cases, two or three weeks' time may be required to reach a probable diagnosis, or to learn that the patient needs surgical attention. In quite a number of these cases, if the lesion is favorably located, that is, in the pyloric end, and metastases are not too extensive, resection may be done, or, with adverse conditions for resection, the physician should know at least, and prior to the incision, that a gastro-enterostomy is probably indicated. The chief points to be observed in these various classes of cancer patients regarding operations are: (1) that the physician should be reasonably certain of the presence of cancer; (2) he should

[5] Deaver: Bost. Med. and Surg. Jour., Oct. 11, 1906.
[6] Mayo: Jour. Am. Med. Asso., April 7, 1906.

usually know when the case is beyond surgical relief; (3) in cases which he considers operable, he should have a pretty good idea that the conditions warrant at least a palliative, perhaps a radical, operation. Ulcer cases with stasis may be included here. Some of them cannot be differentiated from cancer by medical means. (4) In certain cases, either early or late, he should know if the cancer is located at the cardia, or lower end of the esophagus, and be aware that no operation, except a gastrotomy as a last resort, should be attempted. In advising regarding operation, the patient's age and his physical condition are features which should be duly considered.

The above classes of patients (and Hoffmann [7] figures it that the disease has then been present ten and three-tenths months) constitute the vast majority, perhaps 95%, of all gastric cancers as seen by the consultant.

In the remaining small portion of cancer cases, the true conditions perhaps cannot be learned by medical means within three weeks' time. In most of these cases, perhaps all, a surgical exploration should certainly be made, and the operation carried out which seems indicated. But even in these cases a radical operation cannot be done, unless the lesion is favorably located. Sometimes the surgical diagnosis will be negative and sometimes mistakes will be made. Mistakes are also made by the medical man. Thus far those of the writer have been in the nature of commissions rather than omissions. They have resulted from one chief cause, lack of sufficiently close and long observation of the patients. In private practice this lack of observation has occurred only in those cases in which it was felt that the physician, referring the case, expected a positive or negative diagnosis from a *single* examination. This source of error in diagnosis has now been eliminated.

If a physician desires a tolerably accurate diagnosis and the best advice from the consultant, he should turn over his patient absolutely, until such time as is required for the final report. Sometimes three days, at other times three weeks, might be required for this report, but not a longer period. A reasonable length of time must be granted for the carrying out of the various tests. In some cases more time may be required to exclude cancer than is needed in other cases to make a positive diagnosis.

For example, at the first visit an absence of HCl, and other symptoms may point to cancer, yet one or two weeks' observation and proper treatment may show, by a return of the HCl, that the case was one of chronic gastritis or simple achlorhydria. Had the case proven to be cancer the diagnosis might have been made in shorter time.

In concluding, it may well be stated that cancer of the stomach should *more often* be thought of by the physician in his diagnosis of gastric disorders, and at an earlier stage of the disease. It is to him that the choice of methods of diagnosis is necessarily left.

Case.	Age.	Duration months.	No. of days observed.	Loss during observation.	Diagnosis on day.	Operated on day.	Operation advised.	Duration of life after gastro-enterostomy.	Duration of life.	HCl.

This table of 10 cancer cases may give one a general idea of loss of weight during observation, time required to make diagnosis, etc.

Case A is included on account of early age, etc.

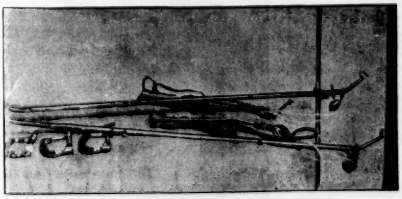
A PORTABLE TRACTION AND RETENTIVE APPARATUS FOR USE IN FRACTURE OF AND OPERATIONS ON THE LOWER EXTREMITY.

BY ROBERT SOUTTER, M.D., BOSTON,
Assistant Surgeon, Children's Hospital; Member of the American Orthopedic Association.

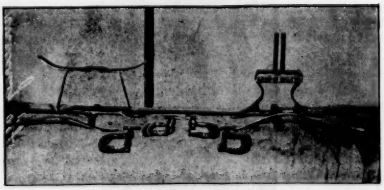
THIS apparatus was devised by the writer for fractures of or operations on the femur or leg or hip-joint. It is often important to overcome contraction of the muscles or prevent overriding of the ends of the fractured bone, and at the same time maintain a good relation of the femur to the pelvis as well as a perfect alignment of the leg.

The proper relations must be maintained while considerable traction is employed. Where manual traction is all that is necessary, even this is hard to maintain with uniformity for any length of time.

Moreover, it is difficult to obtain good counter traction. It is difficult to keep the patient steady during manipulation or during the application of retentive appliances, whether this be plaster of



[7] Hoffmann: Mitteil. a. d. Grenzg. der Med. u. Chir., Jena, vol. xlvii.



I. Apparatus applied showing traction to both legs with room for the application of retentive apparatus or plaster of Paris.

II. Apparatus applied showing traction to both legs. (Side view.)

III. Traction rods, pulleys, traction, leggins, clamps.

IV. Stand for the shoulders, stand for the pelvis, clamps to fasten them to the table.

Paris or ordinary splints and bandages. At best, improvised methods of holding the shoulders, spine and pelvis, with or without traction, are difficult when a good position is desired.

Many of you are familiar with other forms of traction apparatus, some of which may be seen at the Children's Hospital. These are very perfect in mechanism and are all that may be desired in a hospital, but they are not easily transported. The one before you has proved useful in operations where a strong, efficient and portable apparatus is necessary. While it has been devised for and used in adult cases it is also applicable to children.

It is so arranged that traction can be applied or let up instantly; and during traction the leg manipulated or moved in any position. The shoulders, the spine, the pelvis and the legs are held in position for any length of time, and the apparatus cannot be upset during forcible movement or while a plaster of Paris bandage is applied from the axillæ to the ankles. It is fastened to an ordinary operating table or to a broad or narrow wooden table.

By removing the cross steels and placing a small stand, made for the purpose, between the pelvic and shoulder pieces, the apparatus may be used for certain forms of simple jackets in curvature of the spine or in Pott's disease. It can be carried in a dress suit case and considering the strength and power of the machine, it is not heavy.

In fractures of the femur, absence of shortening depends probably more than anything else on the length obtained at the first application of apparatus and maintained afterward by pull and splint.

During the wiring of old fractures of the neck of the femur, in congenital hip manipulation for traction and maintaining position after subtrochanteric osteotomy, for osteotomy in deformities from badly united fractures and in some other instances, this apparatus is useful.

A BRACE FOR POSTURAL CURVATURE OF THE SPINE.

BY ROBERT SOUTTER, M.D., BOSTON,
Assistant Surgeon, Children's Hospital; Member of the American Orthopedic Association.

THE apparatus before you has been used for two years and has answered the purpose for which it was designed, namely, to prevent lateral displacement of the shoulders and the postural part of a rotation of the shoulders on the hips.

I. Position without the brace — lateral displacement of the shoulders to the right.

It consists of a curved pad for pressure on the

II. Brace applied. The shoulders held squarely over the pelvis with slight over-correction.

III. Side view of the brace in position.

chest bone behind and laterally, and another on the opposite pelvis above the trochanter, the two connected by peculiarly curved steels, one anterior, one posterior. They do not rest on the body to make pressure. The anterior steel is disconnected from the hip pad by a self-retaining catch. The pelvic pad has an arm jointed at the hip which extends down to the thigh band. This arm stands out from the thigh when the thigh band is loose. By the shape of the body steels the leverage is transferred so as to throw the chest forward as well as laterally.

This brace will not take the place of complicated braces and jackets. It will be found efficient for certain postural cases when it is undesirable to weaken the muscles by cumbersome and more extensive apparatus. It does not show through the clothing, remains in place and is adapted for active cases with postural lateral deformities.

Clinical Department.

REPORT OF A CASE OF DISSECTING ANEURISM WITH RUPTURE OF THE AORTA; AUTOPSY.

BY W. E. PAUL, M.D.,
AND
W. A. BROOKS, M.D., BOSTON.

The textbooks fail to give a good description of the clinical features of dissecting aneurism. Our record of one case may, we hope, be of value if an attempt is made sometime to depict the symptomatology which must necessarily be based on a number of complete histories and post-mortems. Up to the present time both Allbutt's statement that "it is known only after death" and Stimpson's that "it cannot be recognized with certainty during life," seem to hold good.

The patient was a hard-working merchant, fifty-seven years old, of a rugged type, who up to five years ago drank alcohol freely and continuously. He was an inveterate cigarette smoker and used much coffee. Twenty years ago he contracted specific disease. Ten years ago he had pneumonia. Three years ago he had a severe appendicitis and delayed consent to operation till it was most urgent. A fetid, gangrenous, sloughing remnant of appendix in a purulent cavity, walled off by adherent intestines, was found by Dr. Brooks and successfully removed. A large hernia has occupied the site of operation on the right side of the abdomen since, but has been controlled fairly well by a belt.

For a few weeks previous to his fatal attack the patient had complained of being below par, and had a frontal sinus infection treated by Dr. F. C. Cobb. His digestion was not so good as usual, and he thought he was drinking too much coffee.

The day on which the final sickness began he was feeling very well and ate a hearty lunch of oyster crabs, apricot pie and coffee. He then took part in a game of cards, and at the end of an hour's play got up to take another chair, when he was suddenly seized with severe pain across the lumbar region, not more marked on one side than the other, and extending upwards and outwards toward the scapulæ, but not going toward the abdomen. He described it as a "red pain." It was so severe that he could not go on with his game and was taken to a bedroom and attended by Dr. Buck. Dr. Paul saw him about fifteen minutes after the onset; the patient was then sitting in a chair, moving to and fro, and complaining of nausea. The pain continued and was dull, steady and boring in character. There was a sense of anxiety in the patient's look and manner. It was considered probable that acute indigestion accounted for the condition of the patient, and efforts to relieve the stomach (drinking warm water) were rewarded with fairly free vomiting of sour-smelling stomach contents. The pain, though somewhat less, remained in the back, and the patient could not lie down, as that position was uncomfortable. Later there were two or three attacks of vomiting, with considerable vomitus. A glass of Hunjadi water was taken, but was vomited in a short time. As the pain continued severe in the back, about three quarters of an hour after he was first seen a quarter grain of morphia was given subcutaneously. The patient then felt as though a movement of the bowels was imminent, but two or three enemata gave little result and no gas was passed. A half hour after the first dose of morphia, a second like dose was given and in the course of ten minutes the pain was much relieved. About two hours after the onset he was able to go down stairs and drive home in a cab.

During all this time he was pale and his pulse did not change.

At his home he vomited once or twice and expressed himself as feeling more comfortable than at any time since the onset of the attack. He vomited occasionally, and two or three times considerable amounts were regurgitated.

Seven hours after the onset the pain, never entirely absent, had moved up higher in his back, between the shoulder blades, and was more a discomfort and burning feeling than a decided pain. A hot water bag made it bearable.

Two hours later and nine hours after the first pain there was an access of most severe, dull, steady, constant pain in the lumbar region at the site of the first pain. He groaned with every breath and sat up in a chair by preference. A ½ gr. hypodermic of morphia was given as soon as possible, and relief was most marked in the course of ten minutes. It was found then that no gas had been passed, that vomiting had continued at intervals, that the pulse was 100, that there was evidence of shock with marked pallor; and it seemed that instead of a simple case of indigestion, some more serious trouble existed which was obstructing the bowel.

Dr. Brooks was summoned in consultation, and agreed that the case was a serious one and that the trouble might be due to the bowel being caught under some band. Physical examination of the abdomen revealed absolutely nothing abnormal, however, and the limitation of the pain to the back was confusing to our diagnosis in considerable measure. Laparotomy was most seriously considered, but was deemed unwise by Dr. Brooks.

Five hours later a saline cathartic was given, but was promptly vomited.

Eighteen hours after the first pain the pulse was 120 to 140 after going to stool; there was decided pallor and some pain persisted in the back. For the first time there was a slight pain in the abdomen over the descending colon. It was slightly tender, but did not cause the patient to shrink on palpation. Two high enemata brought away a moderate amount of fecal matter, but there was little gas escaping at the same time. The temperature was normal continuously from the onset of the pain. During the morning (some twenty hours after the initial pain) hiccough lasting a few moments at a time had recurred. Also there had been some spells of dyspnea lasting for a half dozen

breaths at a time. The patient was carried to the Bay State Hospital and seemed refreshed by the trip. Soon after his arrival high enemata were resorted to again, and considerable mucus, some of it stained slightly with blood, was the chief result.

There was now hardly any pain, but the patient said he by no means felt right. That night he slept fairly and was comparatively comfortable the next day. Small quantities of milk and lime water were retained. The day after entering the hospital a high enema was very successful in bringing away considerable fecal material and gas. It was now assumed that at least the bowel's patency was established. A considerable degree of pallor continued, however; the pulse did not fall below 104 and was unsteady at times, though fairly strong. Hiccough and spells of shortened breath recurred. The tenderness on the left side of the abdomen was a little less marked.

Dr. Franz Pfaff saw the patient at the end of the second day and was of the opinion that an internal hernia or intussusception had occurred but had been greatly relieved. The shock he believed to be an indication that the sympathetic ganglia had been pressed on by the affected intestine.

The condition was little changed for the next two days except that the third night in the hospital there was more shortness of breath coming and going in such a way as to resemble the Cheyne-Stokes type. The temperature ranged from normal to 100°. The urine was normal and fairly abundant, in quantity reaching 50 oz. in twenty-four hours.

The fourth night in the hospital there was an uneasy feeling in the back, as though lame. He could not get into a comfortable position; rubbing relieved for a short time only.

The next day hiccough was rather constant, though he ate more and had a satisfactory movement of the bowels and was rather brighter. He was weak and said he was not right. The uneasy grumble continued in the lumbar region, not more on one side than on the other at any time, and was a source of a good deal of uneasiness and restlessness. Later a menthol liniment relieved him and he slept well for the night.

On the morning of the fifth day of his illness he expressed himself as feeling better than at any time since the onset. He ate a fair breakfast and was so comfortable that after the meal he took a short nap. He answered the inquiries of the nurse cheerily. He sat on the side of his bed in the act of passing his water when he suddenly gave a piercing scream, audible all over the hospital, and grasped his right loin with his right hand, exclaiming in agony; he fell forward, but was caught by the nurse, and after one or two gasps, life was extinct.

It was, of course, now realized that a large internal hemorrhage had been the cause of the final catastrophe. Fortunately, permission for an autopsy was obtained, and Dr. Oscar Richardson's record of the aneurismal findings follows:

The intestines were not obstructed. The peritoneal cavity contains a moderate amount of free fluid blood and the retro-peritoneal tissues are swollen, black red in color, and infiltrated with a considerable amount of blood-like material. About the region of the mesentery the swollen, blood-infiltrated retro-peritoneal tissues bulge forward under the transverse colon. The colon on section is not remarkable. The other abdominal viscera show nothing worthy of note.

On opening the thoracic cavity the right pleural cavity is found to contain an enormous quantity of fluid blood and blood clot, and at a point about where the aorta passes through the diaphragm there is a ragged opening in the wall of the aorta through which the blood has poured into the right pleural cavity and infiltrated into the retro-peritoneal tissues and to a moderate extent into the peritoneal cavity.

On section, the aorta shows, extending along its wall as far down at least as the celiac axis, a black red coat, 2 to 3 cm. thick, which consists of a thick layer of blood-clot-like material apparently resting between the muscular wall of the aorta on the inside and a layer of the adventitia on the outside, limited by the pleura in the thoracic cavity. On section, the intima of the aorta all along its course presents innumerable smaller and larger roughened plaques, fibro-calcareous in instances, and the central portions of many of which show ragged openings which extend into the layer of blood clot and fibrin just beneath the dissected layer of adventitia. At a point in the wall of the aorta just as it passes through the diaphragm there is a ragged opening in the wall margined by arteriosclerotic changed tissue and a ragged interruption in the continuity of the surrounding layer of adventitia, fibrin, and blood clot.

Anatomical diagnosis. — Arteriosclerosis of the aorta; dissecting aneurism of the aorta, with rupture and hemorrhage into the right pleural cavity, the retro-peritoneal tissues, and the peritoneal cavity.

Reviewing the clinical features of the case the pain stands out most prominently of all the symptoms. There were four periods of pain: at the onset, nine hours later, a grumbling discomfort in the back for forty-eight hours before death, and the final death pang. Also there was some pain and tenderness over the descending colon. The pain probably coincided with extension of dissection. Its character and location seem of great significance in differentiating pain originating from dissecting aneurism. The pain was limited to the back and was not more noticeable on one side though it extended across the back and upwards and outwards toward the scapulæ. It was severe, dull, deep aching and boring in character; most distressing and giving rise to feelings of anxiety. The slight pain over the descending colon may very well have been due to extension of blood extravasating in the peritoneum. The final pain immediately preceding death cannot be defined.

Next in importance was the condition of shock which did not disappear at any time, though it varied in intensity. He was pale and his pulse was continuously high after the second attack of pain, except in the last twenty-four hours, when it got as low as 88.

Third, the vomiting was a prominent symptom in the first twenty-four hours of the illness. In the absence of any complaint of indigestion before the onset of the pain it seems fair to assume that the vomiting was due to the aneurismal hemorrhage rather than to coincident irritation by the stomach contents. The vomiting was probably reflex and symptomatic. Of negative value as symptoms was the practical absence of abdominal pain, distension, or anything abnormal on palpation.

It ran its course in five days.

THERE has been an enormous increase in the number of rats in San Francisco, and a bonus is being offered for their destruction. — *N. Y. Med. Jour.*

DYSTOCIA DUE TO FIBROIDS. INTRA-UTERINE DEATH OF FETUS. CRANIOTOMY.

BY JAMES R. TORBERT, M.D., BOSTON,
Physician to Out-Patients, Boston Lying-in Hospital.

Mrs. R. Primipara. Aet., thirty-six.

First seen after ten hours of moderately hard labor, the last six hours of which there had been no progress.

Obstetrical examination showed, externally, an unusually large abdomen; uterus completely filling abdominal cavity. On the anterior surface of the uterus was a firm, movable tumor the size of a large orange; on the right side and fundus, several nodules the size of walnuts, on the left cornu a nodulum the size of a cocoanut.

The fetal parts could not be palpated and no fetal heart was heard.

Feeble uterine contractions were evidenced on palpation.

External pelvic measurements, crestal, 28½ cm. Spinous, 22½ cm. Antero-posterior, 20½ cm.

There was no uterine tenderness.

Internally: head through the brim of pelvis, no fore waters, os dilated 1½ inches. No fibroid involvement of cervix or lower uterine segment.

Internal conjugate not felt.

The maternal pulse was 80, of good quality and regular but as the contractions of the uterus had about ceased and no progress had been made for six hours, operative interference was decided upon.

The patient was prepared with especial reference to asepsis. On account of the possibility of fetal life it was thought best to attempt a forceps delivery. Under ether the os was fully dilated manually and the forceps applied; repeated traction showed no advance of the head so the blades were removed. Introducing the hand by the head, a firm constriction ring was found encircling the infant's neck and shoulders, the ring including the center of the large fibroid on the anterior uterine wall. Carefully stretching the ring the hand passed it and the cord was found pulseless. Very little liquor amnii was present and escaped at this time. Craniotomy with Braun's cranioclast and the Smellie scissors was done and extraction of the fetus accomplished without difficulty. There was no maceration of the fetus showing a recent death. The uterine muscle contracted at once and in ten minutes the placenta came away naturally. Hemorrhage was absent and the uterus behaved well. A large intra-uterine douche of salt solution was given and a minor laceration of the perineum repaired. The maternal pulse rose to 140 during the delivery, but one hour afterwards dropped to 100.

The convalescence was uneventful, save for a slight pyrexia 100.8° F. and a scanty flow of lochia on the third and fourth days. This was met and relieved with copious intra-uterine douches of weak creolin solution followed by ℥iv of 5% alcohol which was left in the uterus. There was no further pyrexia, the lochial discharge continued a trifle more bloody than usual but gradually ceased.

Involution was exceptionally slow; on the third day of convalescence the fundus was an inch below the ensiform cartilage and the fibroids were very easily palpated.

The case without the chart was shown to the students at this time and one of whom made a diagnosis of a full term pregnancy, palpated the fetal head and small parts, but strangely enough had negative results with his auscultation.

The patient was discharged at the end of three weeks, and final examination showed an irregular enlarged uterus extending about one inch above the symphysis. She was advised and consented to, later on, have an operation for myomectomy or whatever seemed best when the abdomen should be opened.

The number of patients with uterine fibroids who pass successfully through pregnancy and labor is really most surprising.

The obstetrical importance of uterine fibroids depends upon their situation,— whether subserous, interstitial or submucous, and whether connected with the upper or lower uterine segment.

Subserous fibroids are of no obstetrical importance.

Interstitial and submucous fibroids in the upper segment of the uterus complicate parturition only by their tendency to produce irregular and feeble pains and thus prolong labor. They are afterwards attended by an increased liability to post-partum hemorrhage, a tendency to delayed involution, and an increased risk of sepsis from sloughing of the tumor. If the tumor growths are not situated at the periphery of the zone of the uterus which dilates, they do not generally give rise to any accident. In the lower segment of the uterus, they offer obstruction to the exit of the fetus; are liable to cause malpresentations and malpositions, and occasionally render delivery by the natural passages impossible.

Rupture of the uterus may take place in healthy uterine structures as a result of mechanical resistance offered to the advance of the fetus, or it may commence at the site of the fibroid where the uterine tissue is particularly thinned.

The conduct of this case with the terminal result naturally raises the query whether, if discovered early enough before the beginning of labor, some operative procedure might not have relieved the condition sufficiently to have accomplished a safe termination of the pregnancy.

The co-existence of a fibroid with pregnancy is not always an indication for operation, but it is extremely desirable to frequently examine women who have such tumors, to note the size, position and rapidity of growth, using such knowledge for the proper conduct of the individual case.

Statistics show that cases of pregnancy complicated with palpably large fibroid growths have a maternal mortality of over 30%, and a fetal mortality of probably 50%.

It has been easy to collect 100 cases of palpably large fibroids complicating pregnancy where myomectomy on the pregnant uterus was performed. In less than 5% was the pregnancy interrupted. The labors have occurred without incident, good uterine contractions have been present and no complications have existed. Subsequent pregnancies have occurred without incident.

Myomectomy is adapted to only certain classes of cases, — where the fibroid is subperitoneal or interstitial, where its size is not too great, and where the uterus may be handled without too much trauma. The hyperplasia of connective tissue in these growths favors the manual separation of the tumor from the uterine walls, therefore rendering operation easier for the existence

of pregnancy. Although Cesarian section followed by enucleation of the fibroid would be the ideal treatment of obstructed labor due to a myoma, yet experience teaches that the great majority of the tumors as so situated are of such character as to render attempt at enucleation hazardous, and for these the Porro Cesarian section, or hysterectomy is imperative.

Those fibroids which have already caused a premature or nonsuccessful labor should be operated upon by enucleation, if possible, when the uterus is empty.

Reports of Societies.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

THIRTY-THIRD ANNUAL MEETING,

HELD AT COLUMBUS, OHIO, OCT. 8, 9 AND 10, 1907.

THE President, DR. HORACE H. GRANT, Louisville, in the chair.

The scientific work was divided into medical and surgical sections.

LOCAL VERSUS GENERAL ANESTHESIA IN RECTAL SURGERY.

DR. G. B. EVANS, of Dayton, Ohio, believed that by using a local anesthetic previous to general anesthesia the amount of the general anesthetic was appreciably lessened; the dread and fear were diminished, also shock and danger. Therefore the combined method of narcosis, less anesthetic, suspending shock incident to conscious dread, as well as anesthetic shock, rendered more complete the operative area and consequently more satisfactory work. It was easy to operate on prolapsing piles, but not so simple to operate on piles above the sphincters, yet they demanded operative interference. Operation for hemorrhoids was serious, often attended by some shock, and the greatest caution should be observed to secure asepsis. He did not think it was best for patients that general practitioners should be taught that aseptic precautions at the time of operation and rest at home for a few days were unnecessary.

DR. BERNARD ASMAN, of Louisville, gave a few reasons for some unsatisfactory results in the treatment of ano-rectal diseases. A correct diagnosis was always a first essential, for without it all treatment was largely guesswork. Of all rectal ailments, anal fissure was ordinarily thought to be one of the simplest and easiest to cure, yet experience frequently proved it to be most unyielding. Ninety-nine out of every one hundred of the laity assumed that all ano-rectal troubles were hemorrhoidal in character, and it was not uncommon for them to approach the physician with a diagnosis ready-made, and to preface a description of the case in question with, "Doctor, I have piles." The doctor was then apt to accept the diagnosis with but a superficial examination, or perhaps no examination at all, and hence failure to afford relief followed. There were comparatively few cases of hemorrhoids, pure and simple; they were usually complicated by other local disease, perhaps requiring attention at the same time if a perfect result was to be expected. Cases were cited in point.

DISCUSSION.

DR. B. MERRILL RICKETTS, of Cincinnati, said that surgical anesthesia should be eliminated as far as possible in all work, especially now as capital operations could be done under local anesthesia. Local anesthesia for the treatment of hemorrhoids should not be denounced, nor should local anesthesia be recommended for all kinds of hemorrhoids. There were certain hemorrhoids that could be removed radically without anesthesia. He cited such cases. The trend of the times was not to put patients to bed for days and weeks for the removal of hemorrhoids, when they could be removed at the office of the surgeon or at the homes of patients with impunity. Hemorrhoids should be properly classified, and each class should receive a separate and distinct treatment, some with and some without anesthesia; some with and some without ligature; some with crushing and some with simple incision.

DR. J. RAWSON PENNINGTON, of Chicago, emphasized the importance of making a correct diagnosis. If a patient had a small contracted anus, with a few painful hemorrhoids, he or she should be given a general anesthetic and operated on. If the patient had a patulous anus, and the hemorrhoids were easily prolapsed, especially internal hemorrhoids, there was no need for a general anesthetic. He described his method of removing hemorrhoids. When the rectum was everted and the hemorrhoids were on the outside, with a pair of scissors they could be removed very readily, the rectum then dressed in extension, and putting into the bowel a rubber-covered tampon. When this was done there was no tissue under stress. Tissue under stress was not in the best possible condition to defend itself against infection.

DR. H. O. WALKER, of Detroit, had operated on a large number of cases of hemorrhoids, and had not yet had serious bleeding from the rectum. Hemorrhoids should be operated on under the same surgical principles as were carried out in operating upon other parts of the body. If there should be hemorrhage, it could be controlled by ligature or hemostatic forceps.

DR. E. B. SMITH, of Detroit, referred to the importance of making a complete and thorough examination. This could not be done under local anesthesia. He had never been able to do it, nor had he seen any one else do it with satisfaction. He had had the privilege of operating secondarily on patients who had been operated on under local anesthesia. He operated on these cases under general anesthesia.

THE FREQUENT INTERDEPENDENCE OF DISLOCATED KIDNEY, GALL-BLADDER TROUBLE AND APPENDICITIS.

DR. EARL HARLAN, of Cincinnati, summarized the salient features of his paper as follows: (1) That dependent pathology, accompanying the primary lesion of dislocated kidney, gall-bladder trouble and appendiceal irritation of a severe nature, is of frequent concomitant occurrence. (2) Many cases have undergone operation for appendiceal trouble or gall-bladder trouble wherein the causal factor was a dislocated kidney, the latter producing pressure interference to the bile outflow or bowel current. (3) All cases presenting for abdominal treatment, complaining of indefinite and recurrent distress, discomfort and pain, the attacks being accompanied with the presence of an excess of stagnant gas at certain points in the bowel, and in which the involvement of the stomach, gall bladder and appendix are more or less equal, should receive the careful consideration of the physician, in order that an accurate differential diagnosis may be made. (4) In the vast majority of cases a freely movable kidney presents no pathology on the part of the organ itself, and this immunity may cover a considerable space of time, after which there may appear symptoms of functional and mechanical disturbance on the part of the stomach, cholecyst and bowel. (5) On

account of the wide and uncircumscribed range of pathologic symptoms produced by a dislocated kidney, it is more often liable to go undiagnosed than are other symptoms producing abdominal lesions. (6) Permanent and complete relief results only from a correction of the primary lesion with its dependent pathology.

THE DISPOSITION OF THE APPENDICEAL STUMP.

DR. B. MERRILL RICKETTS, of Cincinnati, concluded that the stump should be as short as possible. Any one of the pursestring methods is dangerous. Ligation for the firm appendix and extirpation for the soft one were the better methods. Hemorrhage from the appendiceal vessel was a common accident, and one that could be avoided. The escape of feces into the peritoneal cavity was also frequent. Infection from the stump occurred rarely. Adhesions resulting from a denuded stump, or mesocolon resulting from ligature, were of little consequence. Ligature around the stump without mucosa between it and a stenosed Gerlach valve would not cause pain, otherwise it might do so. A more definite classification of the pathologic appendix and its results should be more generally accepted. The mortality in cases with vomiting, ileus, obstruction, peritonitis and distention was much higher than reports would indicate. It was probably as great as 90%, if not more. It was difficult to understand why so few such cases had been reported, and still more difficult to understand why they were absent in the work of one and numerous in that of others. The average per cent of mortality for acute cases (7.50), and the average per cent for chronic cases (1.75) was probably a fair estimate for the work during the last five years. Linen and silk ligatures had more advantages than catgut, without the disadvantages, and should therefore be given preference. Ligatures of any material or character should be transfixed in any tissue, especially within the peritoneal cavity. Stumps of living tissue should be sutured or ligated with transfixion, especially if there were canals of any character within the stump.

DISCUSSION.

DR. H. O. WALKER believed in ligating the stump of the appendix. After tying off the appendix close to the cecum, he disinfected it with carbolic acid and alcohol, and then by means of a pursestring suture covered it up. As long as the suture material was aseptic, it did not make much difference what was used. He had never had a death from hemorrhage in appendicitis, except where it occurred some ten days or two weeks after the operation, due to the sloughing of the omentum, rupture and obstruction from a gangrenous condition of the arteries of the appendix from which the patient died.

DR. A. M. HAYDEN, of Evansville, said that if one used silk or linen in uncomplicated cases, there were liable to be suppurating sinuses as a result. In these cases he would use catgut, which, in infected cases, becomes disintegrated in seven or eight days, and there were no suppurating sinuses following. He used linen in all of his clean cases, but in the infected ones he preferred catgut.

DR. CHARLES STOLTZ, of South Bend, Ind., spoke of the use of the thermo-cautery, and believed if it was used it would afford hemostasis without the unsurgical method of tying off a mass and letting it stick up in the cavity, without knowing what would become of it.

DR. CHARLES A. BONIFIELD, of Cincinnati, had excised the appendix, closed the wound with chromicized catgut, and then covered the surface by bringing the meso-appendix up over it. He had done this for several years, and to his knowledge had never had a patient die from the bowel opening.

DR. RICKETTS, in closing the discussion, said the so-called absorbable ligatures failed in many of these cases, and that there was nothing better than catgut or linen. They could be boiled and thoroughly sterilized. He had done 400 appendectomies, without a serious hemorrhage or infection, and had never had to take a ligature out. He never used catgut in his abdominal operations, but employed Pagenstecher linen for almost everything.

WHEN SHOULD GASTRIC ULCER BE TREATED SURGICALLY?

DR. MILTON R. BARKER, of Chicago, said that all cases of gastric ulcer, regardless of any class in which they might be placed, excepting the neglected class, should primarily be treated medically, but that in the light of surgical achievements in this malady the internist had a double responsibility to his patients. First, to do all his methods could do, and, second, to discontinue those methods before his patient had reached such a condition that surgical methods could not be instituted without undue hazard. When medical and surgical science could thus work together, the treatment of gastric ulcer would have attained the acme of perfection.

THE REMOVAL OF ADENOIDS.

DR. JOHN F. BARNHILL, of Indianapolis, described a safe and rapid method of removing adenoids. The selection of a proper curette having been made, an assistant took the child upon his lap, placed the patient's knees between his own knees, and thus clamped them as in a vise. The child's head was placed upon the left shoulder of the assistant where it was firmly held between the two hands of a second assistant. Neither a tongue depressor nor mouth-gag was necessary. The operator sat on a chair facing the patient, who was requested to open the mouth. The curette was quickly inserted behind the palate, the posterior surface of which it should closely hug until the crest of the instrument pressed firmly against the vomer at its point of junction with the body of the sphenoid. In this position the patient's mouth must be opened to its fullest limit, and the curette would occupy a position in a plane about 45° to the horizontal, when the ample width of the fenestra surrounded the entire growth. Keeping the curette exactly in the center line of the patient's naso-pharynx, the crest of the instrument was pressed firmly against the vault, in which situation it was quickly pushed backward and downward, the cutting blade of the curette closely hugging the entire base of line attachment of the adenoid, which was thus completely severed *en masse* and fell from the patient's mouth when the head was held forward for that purpose. In the majority of cases only twenty or thirty seconds were required to do the entire work after all was in readiness.

THE SURGICAL TREATMENT OF SOME INFLAMED GLANDS.

DR. E. B. SMITH, of Detroit, urged the enucleation of inflamed suppurating glands. Where there was a hernia and the protruding tissue irritated a set of glands, then the hernia and not the glands must be cared for. Where the inflammation had progressed to the stage where resolution could not be brought about by poulticing, or where a simple incision would not affect a cure, and the tissue was broken down, or there was an accumulation of germs, then the only logical procedure was a radical operation. Glands found beyond hope of repair were excised, thus getting rid of a large number of germs, the remaining tissues being treated antiseptically and repaired. Repeated attacks of inflammation rendered the glands weak and susceptible to

disease and suppuration. When the glands were incised the inflammation and suppuration either subsided or became quiescent for a time, and then from a slight trauma became inflamed and suppurated.

GOITER.

DR. GEORGE W. CRILE, of Cleveland, recently made a study of his cases of operations upon the thyroid gland, numbering 152, and he briefly summarized them from the standpoint of the practical management of the surgical thyroid. The development of the surgery of the thyroid is best appreciated by the statement that the mortality from thyroidectomy in simple goiters, in nonmalignant and benign tumors, had fallen from 40% to a fraction of 1%. In his own series, the last 101 such operations had been done without a fatality. The surgery of benign tumors and hypertrophies of the thyroid gland was now placed upon a basis comparable with that of appendicitis in the quiescent period, of gallstones and of ovarian tumors. The mortality from unexpected complications was perhaps one in one hundred or two hundred cases, in the hands of a surgeon experienced in this line. Graves's disease was demanding much further investigation. Excision of the thyroid in Graves's disease broke a pathologic chain and the cure was permanent. In a goiter under observation, if the gland began to grow, it should be promptly excised because of the great possibility of its becoming a malignant growth. Many more thyroid glands should be removed, just as benign tumors elsewhere were removed, to prevent the appearance of a malignant growth.

NEUROSES OF THE BLADDER.

DR. ROBERT C. M. LEWIS, of Marion, Ohio, considered a few of the neurotic conditions which were traceable to the genito-urinary organs, especially those involving the vesical neck and the deep or prostatic urethra. In neurotic bladder troubles he gave first place to hyperesthesia because he believed it was met with more frequently than any other of its order. Mental worry or over-tension of the nerves for a long period might produce a vesical hyperesthesia with a train of symptoms simulating a true cystitis; but, as a rule, if there were no inflammation, the absence of mucus or mucopus in hyperesthesia would give a line of distinction so that cystitis might be excluded as a complication or as a sequel to other diseases of the bladder; there was found no other condition which gave so much mental and physical discomfort as hyperesthesia. Men were quite sensitive when it came to genito-urinary troubles, but if a physician once gained the confidence of such patients, and afforded them relief, they would not run away.

INTRAMURAL TRANSPLANTATION OF THE ROUND LIGAMENTS VERSUS THE ALEXANDER OPERATION OR VENTRO-SUSPENSIO-FIXATION.

DR. CHANNING W. BARRETT, of Chicago, gave a résumé of the work done with intramural transplantation of the round ligaments, and, after comparing it with the Alexander operation and ventrosuspension, presented the following conclusions: (1) The Alexander operation fails because most cases of retrodisplacement are complicated. (2) An operation to be widely useful must open the abdomen for inspection and correction of complications. (3) It should be capable of being combined with the best incision for doing work. (4) It must not create false ligaments which will not evolute during pregnancy and involute thereafter. (5) There must be no abnormal arrangement of natural ligaments which allows them to run transperitoneally. (6) When the round ligaments are ample, the inner, stronger portion of the ligament should be chosen. (7) Operation for retrodisplacement must often be performed after much more operating, and so should not offer any tedious technicalities, such as are found in the external search for the ligaments. (8) His internal inguinal shortening and transplantation of the ligaments through the abdominal wall is submitted for comparison with external shortening of the ligaments, or ventrosuspension operations, as one seeming to meet the essential requirements of an operation for retrodisplacements.

WHAT WE CANNOT DO WITH PURGATIVES.

DR. EDWIN WALKER, of Evansville, Ind., said the action of purgatives was not well understood. Authorities varied widely as to how they affected the human organism. Practically all agreed that they were irritants. Purgatives and infections of the alimentary canal presented the same symptoms, namely, liquefaction of feces, increased albuminous exudate, the formation of gas and pain. The physician used purgatives in chronic constipation, when very few were in the least benefited, and nearly all were made worse. In obstruction of the bowels, both acute and chronic, they did harm, besides, the time lost often decided the fate of the patient. The routine practice of preceding every surgical operation with a purge was absurd. If the operation was not on the alimentary canal, there was little reason for giving it. If it was on the stomach or bowel, they did not render the condition more favorable since they increased bacterial activity. The author had operated on nearly one thousand cases in which the preliminary purge was omitted. The results were as good or better than when they were given. The patients were more comfortable, and suffered much less with tympany. Laxatives were rarely required after operation, as the bowels would move as soon as it was necessary. Patients did better without them. Purgatives were useful, but should not be given in a routine manner. They should only be given when there were clear indications.

PERINEAL SECTION FOR OBSTRUCTION OF THE PROSTATIC URETHRA.

DR. CHARLES E. BARNETT, of Fort Wayne, Ind., summed up the cause and effect of acute retention of urine. He considered catheterization more dangerous than operation. He believed that bladder drainage through a median perineal section was the operation of choice. Patients who were practically moribund recovered following improved operative technic with a minimum quantity of anesthetic, oxygen inhalation post-operative, Fowler's position, aspiration irrigation with large drainage tubes, and out-of-bed posture second day. Simplicity, but thoroughness, in the post-operative treatment was the *desideratum*. He reported several cases.

EARLY DIAGNOSIS AND REMOVAL OF UTERINE FIBROIDS.

DR. A. D. WILLMOTH, of Louisville, made a plea for the early removal of these growths. He expressed the opinion based on the statistics at hand and his personal experience that it was the duty of the surgeon to remove uterine fibroids as soon as they were diagnosed, unless some constitutional disease or diseases existed that made operative procedures inadvisable because of the risk involved, or where the surgeon had to deal with a young and childless woman who desired a child, or in those in whom the tumor was subperitoneal, small, and giving no trouble.

TREATMENT OF PUS TUBES.

DR. JOHN E. CANNADAY, of Hansford, W. Va., said that operative and non-operative treatment had their

separate and distinct fields. The trend was toward that form of conservatism which really conserved. Extreme and over-conservative measures were as much to be deprecated as early radical extirpation, late and often. Surgical sense, judgment, ability, skill and experience were needed, so that practically pus tubes should never be removed during an acute attack. Many cases would resolve and be restored to normal conditions by waiting. The author made a clinical classification of cases as follows: those that resolved early, those that were followed by obliterating and crippling adhesions, and, finally, those in which large collections of pus were encapsulated and became sterile. In the latter class the best operative results were given. If the operative field was soiled with pus, that was known not to be sterile, a vaginal drain should be inserted, but not an abdominal drain, as the danger of wound hernia was too great. The author reported 100 cases in which laparotomy was resorted to for chronic pus tubes, with a mortality of 1%.

TREATMENT OF INGUINAL HERNIA IN CHILDREN.

Dr. Frank B. Walker, of Detroit, said it was estimated that one third of all herniæ occurred in children under fourteen years of age. In a series of 700 observations reported recently by Corner, it was noted that multiple herniæ were far more frequent in children than in adults. Premature children were very liable to hernia at birth, and inguinal hernia was present on both sides more often than at full term. From observations it would appear that the causes of hernia formation were more operative in earlier years than in adult life. He believed that it was good surgery to use conservative methods for herniæ in children up to five years of age, and thought the majority could be cured thereby; but for the following class of cases, radical measures should be adopted: strangulated hernia; irreducible hernia; hernia associated with hydrocele or undescended testis; hernia threatening strangulation; those which are uncontrolled or painful under truss treatment, and hernia in children over five years of age.

POST-PERITONEAL FIBROID TUMORS OF THE UTERUS.

Dr. Rufus B. Hall, of Cincinnati, reported cases and exhibited specimens. He had had a large number of post-peritoneal tumors to remove. Some of the operations had been very complicated, while others had been comparatively simple. Some of these tumors were easily enucleated, even when large. By following the line of cleavage the surgeon was able to enucleate them without much difficulty. In others it often required great courage and skill to successfully remove them. Some were so firmly attached to the blood vessels and ureters that to successfully remove them was practically impossible. Such a case occurred in the practice of Dr. I. S. Stone, in which he had the misfortune to lose his patient from hemorrhage before he was able to enucleate the tumor. In many of these cases the surgeon began the operation under the impression that he was going to remove a fibromyoma of the uterus. The tumor might be the size of an adult head, filling the pelvis full and extending somewhat into the abdomen, or it might be very much larger. Even after the abdomen was opened and the tumor examined, it was not possible from the condition present to differentiate between post-peritoneal fibromyoma and sarcoma. The author had made the mistake in beginning to enucleate a tumor, believing he had a fibromyoma of the uterus, when in reality it proved to be a sarcoma.

OPEN METHOD OF TREATING FRACTURES.

Dr. Duncan Eve, of Nashville, said that in all cases in which marked comminution of the fragments was present, and when reduction was impossible, in oblique and spiral fractures of the bones of the extremities, operation was justified. Many of the deformities, pseudarthrosis, and loss of function, which follow fractures, would thus in many cases be obviated. The unsightly deformities which so seriously destroyed the usefulness of the part and predisposed to refracture would be prevented. Fractures complicated by severe injury to adjacent structures urgently demanded operation. Under this heading he included fractures in which pressure was brought to bear on neighboring viscera, nerves and blood vessels, fractures associated with dislocations, and fractures involving joints. By exposing the seat of fracture, the accumulated excess of blood or effused serum could escape, and at the same time permit the removal of any soft tissues that might be between the ends of the bone. In a case of comminuted fracture the surgeon could remove loose fragments of bone which had become entirely separated from their periosteal covering. The technic, after obtaining thorough cleanliness, was to make an incision sufficiently large to enable the surgeon to deal effectually with the fragments. The author reported two interesting cases. Operation should be deferred, if feasible, until after the acute symptoms of the primary injury had subsided, namely, from four or five days to a week. Operative treatment should be adopted in compound fractures; also in cases of a crippled fellow limb, of physical or business demands, of deteriorating personal discomfort, and of prospective activity of a perplexing nature, the wisdom of operation could well be considered. Prospective impairment of function and embarrassing delay in recovery invited the consideration of active interference. He was opposed, however, to the policy and the practice of those surgeons who operated only because a bone was broken and irrespective of present dangers or the future benefits to the patient.

THE OPSONIC TREATMENT IN GONORRHEAL ARTHRITIS.

Dr. A. Ravogli, of Cincinnati, reported two interesting cases in which excellent results were obtained by the injection of gonococcic vaccine.

The following papers were also read: "The Differential Diagnosis of Duodenal Ulcer and Gallstones," by Dr. W. D. Haines, of Cincinnati; "Operations on the Gall Bladder," by Dr. Alex. C. Wiener, of Chicago; "Internal Rotation and Lacerations of the Perineum," by Dr. George B. Twitchell, of Cincinnati; "Plastic Tubercular Peritonitis; Report of an Unusual Case," by Dr. Chas. H. Parkes, of Chicago; "Plastic Work on the Urethra; a New Operation," by Dr. G. Frank Lydston, of Chicago; "Sterilized Hands by Total Absolute Abstinence the Only Factor in Perfect Success," by Dr. J. Henry Carstens, of Detroit; "Retroversion and Retroflexion of the Uterus, Causes, Consequences and Treatment," by Dr. Hannah M. Graham, of Indianapolis; "Gonorrhea and Marriage," by Dr. T. M. Reade, of Springfield, Ohio; "Fracture of the Patella, with Report of Six Cases," by Dr. Robert Carothers, of Cincinnati; "Delayed Union in Fractures," by Dr. Chas. Stoltz, of South Bend, Ind.; "Torticollis, Some of its Various Phases," by Dr. Reginald H. Sayre, of New York City; "The Preparation and Post-Operative Care of Surgical Cases," by Dr. L. G. Bowers, of Dayton, Ohio; "The Surgical Treatment of Acute Intestinal Obstruction and Report of Cases," by Dr. W. A. Melick, of Zanesville, Ohio; "Volvulus of the Entire Mesentery of the Small Intestine, with Report of a Case," by Dr. C. E. Briggs,

of Cleveland; "The Sigmoid Factor in Pelvic Diseases," by Dr. J. Rawson Pennington, of Chicago; "Internal Strangulated Hernia," by Dr. E. M. Brown, of Chicago.

MEDICAL SECTION.

ADDRESS IN MEDICINE.

DR. GEORGE F. BUTLER, of Chicago, in this address, discussed the medical men and their influence on human progress, and said that if we were to prevent disease as the chief mission, or as the most effective method of warfare upon this chief enemy of human progress, the conditions must be known, not merely the material, mechanical and social, from which they resulted, but the primary conditions that lay still farther back of the immediate conditions that resulted in diseases.

He discussed the relations between physicians and the public service, and gave considerable attention to the need for a better understanding of the social question, and deplored the danger to innocents of silence and secrecy. He advocated the abolition of state lines with reference to medical practice regulations. Referring to expert witnesses in legal cases, he condemned "expert liars" in strong language. In the medical profession, as in religion or science, the perils of dominating influence could not be escaped. While the evils flowing from industrial concentration could be met, the evils that followed the syndication of intelligence could not be avoided. The struggle of the ages had been the emancipation of truth from authority.

(To be continued.)

MEDICAL JURISPRUDENCE SOCIETY OF PHILADELPHIA.

STATED MEETING, OCT. 21, 1907, AT 8.18 P.M.

DR. WILLIAM M. L. COPLIN in the chair.

EXPERT TESTIMONY FROM THE LAWYER'S STANDPOINT.

ADOLPH EICHHOLZ, Esq., of the Philadelphia bar, read a paper with the above title. He gave a brief analysis of the functions performed by the lawyer and by the expert in the administration of justice. It is admitted that human reason and ingenuity have not yet been able to devise any system through whose operation actual justice will be insured in every litigated case. In cases where there are disputes as to facts, one side or the other may be untruthful in its allegations; or it may be that the two sides have honest differences, which disagreements may be accounted for by differences in perception. Examples of rules intended to hold the scales of justice evenly balanced were cited. The method of trial of causes was indicated in a general way and the position of the expert witness portrayed. The expert, though sworn as a witness, is in reality not a witness. He does not in general testify as to facts, but is supposed to aid the jury in drawing its conclusions by giving his opinion upon certain facts already testified to. He in a measure stands in the same position as the judge who gives his opinion upon the law, but with the vital difference that the Court's conclusions upon the law must be accepted, while the expert's conclusions are not binding. In the case of the expert scientist there is not only the element of honesty and truthfulness which applies to every witness, but there are also to be considered questions as to whether the theory upon which the witness bases his conclusions will stand the test of later scientific research, and whether the witness has used proper care in his investigations in the case under consideration. The danger of the expert becoming an advocate for the side employing him was referred to. Most of the remedies proposed for the improvement of the position of expert testimony were said to relate to what might be called scientific judges who are not employed by either side, in the supposition that some degree of impartiality might be obtained. The suggestion is made, however, that since so much of so-called science is empirical it is doubtful whether an expert should be given such authority as to make his judgment theoretically or practically conclusive.

WILLIAM W. SMITHERS, Esq., emphasized the statement that the expert should not be considered a witness, describing his position rather as a supporter of the mentality of those engaged in the determination of the issue, an assistant merely, the force of which assistance is only secondary to the cause or issue at stake. He thought the tendency prevailed in many causes to magnify the position of the expert, as did the expert as a rule magnify the importance of his particular part of the trial.

DR. WILLIAM S. WADSWORTH strongly urged that the medical expert should have the same recognition and treatment as a legal judge and that there should not be the effort made on the stand to discredit him. The work of the expert in observing facts and in drawing right conclusions was declared to be a necessity. The conditions, therefore, under which the courts worked should be improved.

DR. HENRY BEATES, JR., thought the interest in the question, on the part of the expert, centered around knowledge and honesty, and these two properties too often became the subjects of attack and perversion. The system also of utilizing expert testimony was regarded as often so defective that persons totally unfit were allowed to qualify as experts. He questions whether it is not a faulty method that permits expert testimony to be given by a physician who is interested in the case. Regarding the point made that an exeprt, though sworn as a witness, is not in reality a witness, but one whose function is merely to give an opinion, he believes the sooner such rule is dispensed with the better will it be, since opinions are influenced by environment. He believes that the system of utilizing expert testimony in the bringing of experts on each side, who in a degree must become advocates of their respective sides, emasculates the entire system of its value.

JOHN H. CLARK, Esq., believes that ultimately some method will be devised by which expert testimony will be more satisfactorily made use of. One difficulty in the subject is the kind of men usually found in the jury box.

PASCHAL H. COGGINS, Esq., thought that experts were falsely regarded as impartial witnesses. This impartial position he believes impossible in matters of opinion, the result of special study and long training. The expert should occupy rather the position of counsel, and having reached a conclusion should be at liberty to support it by all his reason and knowledge, and to meet the opinions of the expert on the other side.

DR. HENRY LEFFMAN pointed out that there were two sides of the question and that the expert is largely influenced by the opinion of the individual he represents and the aspect in which he views the case. An illustrative case, and one in which it would seem that experts might have taken either side, was that concerning the taxing of an electrical company upon the ground that it was a manufacturing corporation. In

this case the question arose whether or not electricity was a manufactured product. He believes, on the whole, that the present system of expert testimony is the best and that in the friction of the opposing expert the sparks of truth are ultimately brought out.

Dr. Wilford W. Hawke referred to a commission in the city of St. Louis, composed of physicians who had banded together to give expert testimony free of charge to the city. He cited a case in which two physicians appeared in court as experts and yet who, when their qualifications were questioned, were obliged to say that they had never seen a case of insanity. He spoke of his experience in a recent murder trial in which the Court would not allow him to qualify his statements, which in print might not convey his meaning, upon the ground that he could not give a "medical lecture" in court. The term "psychic epilepsy" had been used, and although both sides agreed as to the mental status of the man, the jury paid no attention to the medical testimony and convicted the prisoner.

Haines D. Albright, Esq., outlined the plan by which experts were obtained for the opposing sides, and thinks that with the evidence brought out in direct and cross examination the system in the long run proved its value.

Dr. John B. Roberts deprecated the present tendency for the fee of the medical man to depend upon the result of the case.

John H. Clark, Esq., thought that a lawyer who takes a contingent fee, pays a fee to a man bringing him a case, or pays a physician for proving his case, cannot be an honest man and ought to be sent to jail.

Mr. Albright spoke in favor of a contingent fee, under certain circumstances, for example, where the party is too poor to pay an attorney and the lawyer assumes the risk of not being paid at all.

Mr. Eichholz, in closing, admitted that it was sometimes difficult for a professional man to express a professional opinion in other than technical words, but urged that the medical man in his expert testimony should remember that he was expected to explain certain things of which others were supposed to know nothing, and that so far as possible technical terms should be eliminated.

An objection to the suggestion that the expert should occupy the position of counsel was the difficulty of having a deciding authority upon the point at issue between the opposing experts.

While the present system of expert testimony may not be ideal Mr. Eichholz believes it the best that so far it has been possible to devise. It is a means of getting at the truth and of deciding disputes. With some method of raising professional standards there would come the possibility of raising the standard of the expert testimony.

Book Reviews.

Essentials of Chemistry and Toxicology. By R. A. Witthaus, A.M., M.D., Professor of Chemistry, Physics and Toxicology in Cornell University. Thirteenth edition, revised by R. J. E. Scott, M.A., B.C.L., M.D. New York: William Wood & Co. 1907.

This small book has been popular with those who have wished to get a general idea of chemistry and toxicology through a system of questions and answers. This thirteenth edition differs somewhat from the preceding ones, particularly in the portion devoted to organic chemistry which has been rearranged and partly rewritten. Of its kind it is one of the best books with which we are acquainted.

Hay-Fever, Hay-Asthma, Its Causes, Diagnosis and Treatment. By William Lloyd, Surgeon-in-Charge of the Nose, Ear and Throat Department, Kensington General Hospital, etc. London: Henry J. Glaisher. Chicago: W. T. Keener & Co. 1907.

This small treatise on hay fever is well written and follows in general commonly accepted views. The author has definite ideas, but they are neither eccentric nor particularly new. His view of the etiology is the familiar tripod, — hyperesthesia, disordered reflexes and the specific irritant. He can detect the hypersensitive areas by sight as well as by touch, and he treats them with the cautery. During the attack he finds the mucous membrane extremely red, where others note that it is commonly anemic. In referring to the work of Dunbar, he apparently misses the interesting theory that the etiological fault in the hay-fever victim is chemical rather than nervous. In regard to treatment there are many suggestions, and several cases are reported cured by cauterization.

A Practical Treatise on Fractures and Dislocations. By Lewis A. Stimson, B.A., M.D., LL.D. (Yalen.), Professor of Surgery in Cornell University Medical College, New York; Surgeon to the New York and Hudson Street Hospitals; Consulting Surgeon to Bellevue, etc. Fifth edition, revised and enlarged; with 325 illustrations and 52 plates in monotint. New York and Philadelphia: Lea Brothers & Co. 1907.

Stimson's great volume of 854 pages is the worthy successor of that by Hamilton, another eminent Bellevue surgeon, who was publishing twenty-five years ago. Stimson's book is addressed to the general practitioner as well as to the surgeon, and is an encyclopedia of the latest and most useful information on his subject. In this fifth edition the author points out especially the notable increase in our knowledge derived from the x-ray, though he might well emphasize the possibility of a fallacious interpretation of x-ray plates by inexpert observers, as well as the danger in trusting for final diagnosis to the cheap commercial x-ray apparatus commonly used by general practitioners. We commend his use of massage in the treatment of fractures, and suggest the great value of the Zander apparatus in restoring function to crippled and contracted joints.

Fractures of the carpal and tarsal bones, dislocations of the semilunar, and fractures of the upper end of the radius receive appropriate consideration. But an extensive review of this valuable work would be inappropriate in this brief writing. Suffice it that the book should be bought and studied by surgeons and general practitioners.

Manual of Diseases of Ear, Nose and Throat. By JOHN JOHNSON KYLE, B.S., M.D., Professor of Clinical Otology, Rhinology and Laryngology in the Medical College of Indiana, etc. Second edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co. 1907.

A review of the first edition of this book appeared in the JOURNAL of Jan. 31, 1907. This early call for a second edition is proof of its acceptance as a satisfactory textbook. A few additions have been made, especially a chapter on the diseases of the trachea and bronchi.

Tracheo-Bronchoscopy, Esophagoscopy, and Gastroscopy. By CHEVALIER JACKSON, M.D., Laryngologist to the Western Pennsylvania Hospital, the Eye and Ear Hospital, and the Montefiore Hospital. Illustrated. The Laryngoscope Co.: St. Louis, Mo. 1907.

The importance of the recent development of the direct inspection of the air passages and esophagus will make this book welcome, and especially as it comes in so excellent a form. It contains about two hundred pages with many illustrations of real value to the context and a few colored plates showing normal and pathological views of the different regions. It contains a brief history of the subject with a complete bibliography, a description of the necessary instruments and apparatus and the proper methods for their use, the important points in anatomy and the principal pathological conditions which may be encountered. To the compilation of the work of others is added the original work of the author, and the results of his experience. Beginning with the work of Killian, whose instruments and methods established bronchoscopy, the writer introduced the small distal lamp of Einhorn's esophagoscope into Killian's tubes, adapted to receive them.

Incidently Killian had given an impetus to esophagoscopy, and Jackson, finding that the distal light was little affected by the length and small caliber of the tube, continued through the esophagus into the stomach. Here he is virtually a pioneer in a new field. Previous gastroscopes have been complicated and of no practical help in diagnosis, to say nothing of treatment. An outline of what the writer has done in this direction appears here, and a fuller description is promised in a future book.

The author in addition to his ingenuity in the making of instruments, and sound judgment in the treatment of cases, is a master in the arrangement of details, and the clear explanation of these details adds much to the value of the book. The position of the patient and the assistants, the care and handling of the apparatus, the management of anesthesia, are matters which in direct inspection through long tubes make the difference between success and failure. In Europe, the small distal lamp has not yet gained headway; in this country the impetus which it has received is due largely to Jackson. Whether or not this method of illumination becomes universally adopted, there is no doubt that in his hands or under his instruction it is capable of excellent results.

A Text-Book of Embryology for Students of Medicine. By JOHN CLEMENT HEISLER, Professor of Anatomy in the Medico-Chirurgical College, Philadelphia. Third edition, thoroughly revised. Philadelphia: W. B. Saunders Co. 1907.

Professor Heisler's Embryology has met quite successfully the need for a not too elaborate manual for the use of medical students. It is well arranged and clearly written, though it is by no means so accurate as to have complete value as an authority. The titlepage states that this is the third edition, "thoroughly revised." Most of the electrotype plates have been untouched, but here and there a new page has been inserted and occasionally new paragraphs. These are always so grouped as to make an even number of plates, and by this device the old electrotype plates can be largely used for reprinting. The thorough revision, therefore, would be more correctly described as the interpolation of twenty new pages. By this commercially advantageous method, the third edition has really been improved, as the results of some recent investigations have been added to the volume, bringing it nearer to the standard of what such a work ought to be. The intention has evidently been to adapt the book as much as possible to cramming, for pages are everywhere marred by printing the leading words in heavy-faced type. When this is done, we may usually feel pretty sure that neither the author nor the publisher has wished to produce a textbook of first-class scientific excellence.

Lectures on Diseases of the Lungs. By JAMES ALEXANDER LINDSAY, M.D., F.R.C.P. (Lond.), M.A., Professor of Medicine, Queen's College, Belfast; Physician to the Royal Victoria Hospital, Belfast, etc. Second edition, enlarged and rewritten. New York: William Wood & Co., 1906.

The lecture form is retained in this second edition. The lectures on heart disease in the first edition are omitted in the second and the entire space given to pulmonary disease. Practical diagnosis and treatment are the chief considerations, and the work is intended as a supplement to rather than as a substitute for the ordinary textbooks. Methods of physical examination and general symptomatology are considered in the first 128 pages. Pleurisy, empyema, pneumonia and bronchitis occupy about one hundred pages. Pulmonary tuberculosis is discussed in 182 pages, and the balance of a book of 496 pages deals with other forms of pulmonary disease.

The book is written in a clear, simple style. Conflicting theories are discussed in a judicial manner; the author's own opinion is always evident and its basis is usually stated. The discus-

sion of treatment is in accord with present therapeutic tendencies. It is rational and a good mean between the nihilistic tendencies of some and the irrational drugging of others. The limitations of therapy are clearly stated, but there is no pessimism as to the value of treatment. The introduction of definite directions as to dosage and drug combinations which have proven efficacious in the hands of the author would have been an improvement, and might be expected, particularly as the book is in large measure a statement of the author's individual experience. To the younger student this will prove a defect in an otherwise very excellent book. Grocco's sign should receive more than the author's passing mention, for in the reviewer's experience it has proven of much value.

Such a book will not be of great service as a book of reference, but to the reader, whether student or older practitioner, it will bring much information presented in a very practical, common sense form, and of a nature that can be put into immediate use in connection with his daily patients. Typographical errors are very rare in the book. There are no illustrations, but the bookmaking has been well done

A Text-Book of the Practice of Medicine. By Hortba Amory Hare, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College of Philadelphia, etc. Second edition, revised and enlarged. Philadelphia and New York: Lea Bros. & Co. 1907.

The second edition of Hare's Practice appears in enlarged form. The work is a combination of judicious selection from medical writers with original observations and statistics. It is illustrated with numerous original or borrowed charts and pictures. The latter are distinct and illustrative, numerous enough, but still play a minor rôle to the text, as should be the case in a book of this character. The work of revision has been done in a manner to maintain the position won by the first edition, and the newer points of view based on recent investigations have been incorporated.

The book is well printed. The binding might be better, for the reviewer's copy showed defects after but little handling. A heavier binding would have been better for such a large book. However, the massive tomes that the American publishers inflict on the medical public is a just cause for protest. The prejudice among the publishers against handy volumes seems deep rooted. To hold these books while reading is a source of physical fatigue that always detracts from the pleasure of using American texts. Hare's book should appear in two volumes, at least, and a gain in lightness by using a flimsy binding on the one large volume is not a satisfactory substitute. The foreign custom of putting books on the market in paper covers to be bound according to the readers' taste has much in its favor. This criticism, however, is of the publisher, not of the author.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, NOVEMBER 28, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 Boylston Street, Boston, Mass.

RURAL LIFE FOR THE RESTORED CONSUMPTIVE.

One of the most difficult problems related to the anti-tuberculosis propaganda is how to dispose of the convalescent and of one in whom the disease has been arrested. The consumptive is restored to a very measurable degree of health in the sanatorium, the tent-farm or the *colonie agricole;* but to continue him under such salutary influences is either most difficult, or oftentimes quite impossible. Sometimes he is naturally unfit for agriculture; but in deplorably many cases he returns by choice and not by necessity to the baneful conditions under which he has contracted the disease, with the result that the arrested tubercular processes are excited anew.

Those in charge of the French hospitals for tuberculous children have to cope with the unwillingness of their young graduates to do light farming and outdoor work; their preference is generally to return to the slums from which they were mercifully taken when they were grievously ill. On returning to these unsanitary and perhaps vicious environments they are likely to redevelop the lesions that have been healed in the benignant rural atmosphere. At Villiers a *colonie* was established in which convalescents were to be taught farming and gardening; it was greatly hoped that boys restored to health would there become attached to a country life, and would be got away from baneful urban surroundings. It was found, unfortunately, almost impossible to retain them; they would not settle down happily to farm life. At Noisy-le-Grand, where only girls suffering from tuberculosis are cared for, a similar endeavor has been made, with no better success, and for the same reason.

Senator Jules Maline[1] has presented a study of the merits of agricultural as against urban life in France, which well deserves perusal by those interested in similar conditions in America. He recognizes that men will return to the land in great numbers only when the balance of human satisfaction is in favor of the country. It avails little to argue that the wealth of a people lies in its agriculture. "The problem involves much more than the simple question of financial profit and loss; so long as workingmen living in dark tenements forget their sordid surroundings at the sight of parades, picnics, political meetings, cheap theatricals, gay saloons and hurdy-gurdies, while their rustic relatives have to go to bed at seven for sheer weariness and lack of diversions, the cityward rush will not abate."

Other difficulties are revealed in the important report made by the Committee on the Prevention of Tuberculosis of the Charity Organization Society of New York City. It was sought to find places in rural districts for those strong enough to do light work. Farm help is always badly needed; yet the farmers cared little for the work of the convalescent or cured consumptive, except at a very low wage. Healthy men ignorant of farming could be taught; those who knew about farming but were ill could be given light tasks while strength should be returning. But there was no demand for men both weak and untrained, who were driven to soil only by disease. The committee next considered tenant houses standing vacant on farms. Such a house with spring or well water, and a large garden plot, with as much firewood and fruit as would suffice for a family's needs could be had for two or three dollars a month. Among 60 who desired such living conditions, 43 were rejected because of drunkenness, shiftlessness or physical inability; only 10 found places, of whom but 2 were entirely successful, 2 were partly so, and the remaining 6 were failures.

The committee concluded that indigent consumptives can occasionally be placed in suitable country employment with very good results; that comparatively few desire such work sufficiently to apply for it, and that most among such applicants are absolutely unfit, either by medical or social reasons, or both, for such work. Incipient cases in good physical condition can with difficulty be persuaded to give up their city employment; yet tradesmen and artisans who have been consumptives should find most congenial occupation in small semirural towns and villages.

[1] The Return to the Land. Published by E. P. Dutton & Co.

It is furthermore evident that physicians and those concerned with the care of the tuberculous should not send these patients to the country to shift for themselves; nor will any plan be feasible which should lack facilities for the careful adjustment of work to the physical abilities of the individual.

It is, indeed, a strange phase of human nature that city slums, with their squalor and their hideously unsanitary conditions, should be preferred to the restfulness, the peace and the healthfulness of the country; especially is this to be wondered at in the young, who should take most naturally to the fields, birds, flowers and brooks. Strange, too, is the situation when throughout these United States farming is carried on under the greatest difficulty, because laborers cannot be got to till the fields, while many thousands of idle men in cities complain that they are starving; when innumerable small investors are deterred from going into farming by reason in large part of the difficulty of coaxing laborers away from the industrial centers.

It must be explained to those who fear the monotony of country life that rural conditions have vastly changed in the last thirty — indeed, in the last ten—years. "There are hundreds of charming villages from Maine to California which can offer laborers and small farmers almost as many pleasures and social advantages as the large cities can; the spread of trolley cars and telephones has turned vast regions of farming land into suburbs." When we add to these agreeable features, village libraries, clubs, lyceums and the rural free delivery we are well in a position to assure the restored consumptive that in exchanging the vicious conditions under which he has contracted the disease for existence in the country, he has no occasion to contemplate a lonely life.

TUBERCULIN IN DERMATOLOGY.

TUBERCULIN, like any toxin, merely requires to be given in proper doses, and, when once these are known, it can certainly render considerable service. This is what now appears to be transpiring in dermatology, and Schmitt has brought the question up-to-date in his Paris thesis.

It would appear preferable to employ the older tuberculin (tuberculin A. T.) which gives far more distinct reactions than the other preparations, notably than the new tuberculin (T. R.) of Koch. On the condition that the subject to be treated by tuberculin presents no contra-indica-

tions for its use, such as a visceral focus of tuberculosis, especially pulmonary, and if one begins with extremely small doses, such, for example, as one decimilligram, many important diagnostic or topographic indications as to the cutaneous lesion may be obtained. If one progressively increases, and at the proper time, the dose, one will be able to determine that dose which will give rise to a local reaction with a minimum general reaction, which will be the therapeutic dose for a given patient.

It is known that injections of tuberculin produce reactions of two different kinds, namely, a local reaction, which takes place in and about the cutaneous lesions, and a general reaction principally characterized by fever, one or more chills and a general condition of malaise. Schmitt has studied these manifestations and his researches are corroborated by Martial. The latter has used tuberculin, not from the standpoint of diagnosis, but in order to determine the real extension of lupus, for example. The lupomata do not always make themselves manifest by apparent cutaneous lesions. Around a visible focus of lupus there are invisible elements which can only be detected by the use of tuberculin, and from the extent of the reaction produced one may judge of the real extent of the lupus, so that one may treat the diseased surface thus put in evidence, and not merely the apparent lesions.

Unna has used a soap containing tuberculin for local treatment of various cutaneous tuberculoses. It has as a base potassium, to which is incorporated the toxin and is employed *in loco*. Mattan-Larier and Marmorek have advised employing the indirect tuberculin reaction, the principle of which is to employ an animal as the intermediary reactive before injecting in the human subject. Wright and Douglas have employed the T. R. tuberculin, considering it as a stimulant in the production of anti-tuberculous substances or those substances which protect against the attacks of the bacillus, and they have discovered a special substance in the blood which they call opsonin, which renders the elements of the blood apt for phagocytosis. Tuberculinization of an individual will increase the quantity of opsonin contained in the blood, and this new application of T. R. tuberculin is being studied on a large scale, both at home and abroad.

Several theories have been emitted to explain the so favorable action of tuberculin on cutaneous lesions and the so unfavorable on visceral lesions. It would appear that, according to histologic examination, the reactionary inflammation set up by the tuberculin around the tuberculous elements has as an effect to provoke their enucleation, and when the bacilli-containing tissues have been eliminated, cicatrization will take place more rapidly.

Unfortunately, it appears that tuberculin does not possess an absolute diagnostic value. The reaction takes place in nontuberculous lesions, and, on the other hand, this does not take place in all cases of true tuberculous lesions. This question is difficult to settle, because it may be well questioned whether the experimenters have placed themselves in the necessary conditions for the test and also whether the tuberculin that they employed really possessed a power of reaction sufficient or not. Given what we now know of the diagnostic value of the local reaction, it is rather astonishing that Schmitt concludes, with Landouzy, that it can absolutely settle the question in cases of tuberculides, a question that has been recently discussed by Darier, Leredde and Pautrier. Schmitt relates twenty-two cases of lupus and tuberculomata treated by injections of tuberculin and shows that the therapeutic value of this agent in dermatology is still more questionable than its diagnostic value. Certainly, among these cases which are all interesting, there are some where a very great improvement was obtained and a cure in some *nearly* resulted. But to nearly obtain the cure of a lupus means a nearly certain recurrence and in all the cases reported by Schmitt the cure was only temporary and often other medications had to be resorted to. He concludes, however, that the use of tuberculin is quite legitimate in the therapy of cutaneous tuberculosis, either in conjunction with other methods of treatment, or, as a last resource, when all else has remained powerless to control the lesions.

MEDICAL NOTES.

Whooping Cough at Statington, Penn. — It is announced that there are upwards of three hundred cases of whooping cough in Statington, Penn., and that the epidemic is spreading.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Nov. 20, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 51, scarlatina 41, typhoid fever 18, measles 8, tuberculosis 28, smallpox 0.

The death-rate of the reported deaths for the week ending Nov. 20, 1907, was 15.06.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, Nov. 23, 1907, was 198, against 190 the corresponding week of last year, showing an increase of 8 deaths and making the death-rate for the week 16.94. Of this number 94 were males and 104 were females; 195 were white and 3 colored; 111 were born in the United States, 76 in foreign countries and 11 unknown; 40 were of American parentage, 136 of foreign parentage and 22 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 41 cases and 6 deaths; scarlatina, 44 cases and 0 deaths; typhoid fever, 14 cases and 1 death; measles, 12 cases and 0 deaths; tuberculosis, 37 cases and 21 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 25, whooping cough 0, heart disease 32, bronchitis 3 and marasmus 2. There were 15 deaths from violent causes. The number of children who died under one year was 29; the number under five years, 40. The number of persons who died over sixty years of age was 42. The deaths in public institutions were 59.

There was 2 cases and 0 deaths reported from cerebrospinal meningitis during the week.

BEQUESTS. — Among many institutions benefited by the will of the late Lyman F. Rhoades the Lynn, Mass., Hospital received $5,000, the Home for Aged People in Winchester, Mass., $1,000, and the Memorial Home for the Blind in Worcester, $2,000.

ANNUAL MEETING OF BOSTON TUBERCULOSIS ASSOCIATION. — The annual meeting of the Boston Association for the Relief and Control of Tuberculosis was held Nov. 19, and the following officers unanimously re-elected: President, Dr. E. O. Otis; Vice-President, Dr. Arthur K. Stone; Clerk, Mrs. Mary Morton Kehew; Treasurer, George S. Mumford.

DIPHTHERIA IN ROCKLAND, MASS. — One of the schools in Rockland, Mass., has been closed for the second time in a month, because of an outbreak of diphtheria. This school, numbering 400 pupils, is the largest in the town. There are about fifteen cases of diphtheria of a very slight form now under observation.

WORK FOR THE INFIRM. — A meeting has recently been held, in Boston, in which Dr. Joseph H. Pratt and other physicians and laymen are interested, to consider the possibility of making it easier for the physically and socially handicapped to obtain employment. Among those who attended and spoke were Mr. C. C. Carstens, of New York, and Dr. Charles P. Putnam, Rev. Elwood Worcester and Dr. John B. Hawes, of Boston. A committee was appointed for the purpose of considering a permanent organization. Another meeting will be held next month.

LECTURES ON THE PROTOZOA. — Prof. Gary N. Calkins, of Columbia University, is giving a series of eight lectures in the Lowell Institute course in Boston. Five of these lectures have already been given, concerning themselves chiefly with a discussion of the protozoa in their biological aspect. Three lectures remain to be given on Nov. 29, Dec. 3 and Dec. 6, which should be of special interest to physicians. The titles of these three final lectures are: Protozoa and Pathology: Malaria and Sleeping Sickness. Protozoan Parasites of Dysentery, Hydrophobia and Smallpox. Some Doubtful Protozoan Diseases; General Conclusions.

NEW YORK.

CENTENARIANS. — Daniel Ellison, of Freeport, Long Island, N. Y., died on Nov. 17 at the age of one hundred years. He was the oldest resident of Freeport, and as "Uncle Daniel" was long well known throughout the south side of the island and among the baymen and fishermen.

Mrs. Sophia Ackerman, who was one hundred and one years old on Oct. 28, died at her home in Bloomfield, N. J., on Nov. 18. She survived her husband by twenty-two years, and leaves 2 sons, 2 daughters, 12 grandchildren, and 22 great-grandchildren.

JEWISH HOSPITAL SOCIETY.— The annual meeting of the Jewish Hospital Society, of Brooklyn, was held on Nov. 17. Its hospital building was dedicated on Dec. 6, 1906, and from that time up to Nov. 1, 1907, 1,112 patients had been treated. Its present equipment is for 108 beds, but, in full operation, it would have a capacity of 160. The directors have purchased adjoining property, on which it is purposed to build a nurses' home and, in the course of time, an additional wing to the hospital, which will accommodate 100 more patients. The directors have also organized and had incorporated a separate society, The Training School for Nurses of the Jewish Hospital, of Brooklyn.

PASTEURIZATION PLANTS. — Nathan Strauss, of New York, having established at his own ex-

pense, pasteurization plants in Berlin and other German cities, is now devoting his attention to similar work in England, and has offered to give to towns willing to accept them at least twenty-five plants, costing $1,000 each. He has invited Dr. G. Moore, at present Medical Officer of Health, of Huddersfield, one of the great manufacturing towns in the north of England, to devote his entire time, at a handsome salary, to installing and overseeing pasteurization plants in such municipalities as will undertake the cost of their maintenance; and it is understood that Dr. Moore will accept the position.

Examination of Police Officers. — In the New York Supreme Court in Brooklyn, on Nov. 12, Justice Burr rendered a decision to the effect that a considerable number of captains and lieutenants whom Commissioner Bingham had retired from the police force, after they had been examined and pronounced unfit by the Board of Police Surgeons, had been retired on insufficient evidence, and that the reports of the examining surgeons were not sufficiently specific. The judge therefore ordered that the cases should be sent to a jury and that expert evidence be called for. It will rest with the jury to decide, after hearing opinions on both sides, whether the officers are really incapacitated, either physically or mentally, for active service. It is understood that the Police Department will appeal from this decision, on the ground that in the retirement of the officers every step was taken in compliance with the provisions of the city charter.

The Charity Organization Society. — As an appropriate way of celebrating the twenty-fifth anniversary of its foundation, the Charity Organization Society planned and carried out a conference on the betterment of living conditions, commencing Nov. 19, and lasting three days. The opening session was held, in the presence of a large audience, at Carnegie Hall, and on this occasion addresses were made by the President, Robert W. De Forest, Governor Hughes, Mayor McClellan, Jacob H. Schiff representing the United Hebrew Charities, and Dr. Emil Münsterberg, President of the Department of Public Charities of Berlin. The last named, who is brother of Dr. Hugo Münsterberg, Professor of Psychology in Harvard University, had crossed the ocean expressly to attend the conference, going back to Europe on the return trip of the same steamer by which he came over.

A Commissioner of Street Cleaning. — Mayor McClellan has appointed Foster Crowell, a prominent engineer, Commissioner of Street Cleaning, in the place of Dr. Walter Bensel, of the Health Department, resigned. In his letter accepting the latter's resignation the Mayor says: "I part with you most regretfully, and am only consoled by the thought that in the resumption of your life work as Sanitary Superintendent, the city will still have the benefit of your experience, your knowledge and your ability. During the four and a half months of our intimate association I have never been obliged to comment upon your work, except to praise. You have reorganized the Department of Street Cleaning, contented your men, satisfied the public and — cleaned the streets. May your future be as useful and as honorable as your past."

It may be remembered that Dr. Bensel accepted this difficult and trying position only with the distinct understanding that it was only for a period of three months. At the expiration of that time, as the Mayor had not yet been able to fix upon the right man for the place, he consented to serve until a successor had been appointed. As Mayor McClellan intimates in his letter, Dr. Bensel's management of the department has met with the marked approval of the community at large. Assuming the duties of its head at a time when it was largely demoralized by a formidable strike among the employees, which paralyzed the collection of garbage and other work in midsummer weather, he soon brought order out of chaos, and it is generally acknowledged that he has made the most efficient Street Commissioner since the late Colonel Waring, who organized and carried out new plans and methods which have been successfully adopted in various other cities.

2. Collins reviews the history of recent epidemics of this disease, and discusses its clinical manifestations, particularly as observed during the present epidemic in New York

City and its environs. He estimates that already there have been more than one thousand cases, but as yet nothing definite has been learned in regard to the etiology of the disease. A noteworthy feature of the epidemic has been the number of cases in which a fairly good recovery has resulted; that is, in which there has been little or no muscular atrophy. The explanation of this is that the inflammation in the anterior horns is not so intense as to destroy the cell bodies and nutritive processes of the peripheral motor neurons. In order to secure data to aid in investigating the etiology of the disease, Collins urges physicians who see the patients early to send lumbar-puncture fluid, urine and feces to those who are equipped to study them adequately. Later on in the disease there is less hope of discovering facts of importance.

4. Gould says that mentality preceded and created structure. It has been shown that the mechanisms that give man external validity, speech and writing are one-sided. This one-sided differentiation is progressive throughout life. Right-handedness is partially a matter of right-sightedness. In 97% of children the right eye is the better seeing eye. If one is right-handed the centers for writing and speech must be on the left side, and the visual centers on the same side. Pathology follows any attempt to interfere with right or left-handedness. Those persons who demand right-handedness of the left-handed child make him morbid and maladroit. The author gives several very interesting cases of the life-long crippling of the faculties and mechanism of writing resulting from attempts to make a left-handed person learn to use the wrong side of his brain for writing.

1. Germany and some of the other continental countries have used for years a three-class meat system. In this country we have only two classes, — meats passed for unrestricted sale and condemned meats. The additional class, or Freibank class, includes meats which are passed for sale under restrictions. Much of the meat of a tuberculous animal, properly inspected, could, instead of being thrown away, be classed as Freibank and sold. The tuberculous lesions are often localized and can easily be cut out. Certain other meats can be used with safety provided they are cooked. This third class, or Freibank class, would give the poor classes a good safe meat, as it must be inspected, and at a much reduced price. Probably on the removal of the dread of complete loss the local butchers, to whom the federal law does not apply and who are able to sell actually bad meat uninspected, would apply for inspection. Moreover, with the Freibank class the dairyman would get some return for his tuberculous cows, and would be the more ready to co-operate with the movement to eradicate tuberculosis from his herds.

2. Hamill thinks percussion is much neglected in infants and children. He emphasizes the necessity of proper technic. He prefers light percussion, using the finger-finger method, but placing only the terminal phalanx of the percussed finger against the chest wall. Position is of great importance. The two sides must be absolutely symmetrical, with the head straight. The muscles should be completely relaxed, otherwise abnormal dullness from contracted muscles occurs. For percussion of the front of the chest, the infant or child is laid flat on the back. For percussion of the back the child either sits up or is held by a nurse. If too sick for this procedure, the child is turned from side to side, but comparison is made only from the two sides in the same position, *i. e.*, free side with free side. Some of the differences in percussion of infants from percussion in adults are that the apices in infants are relatively less resonant, due to the imperfect development of the apices, that there is no pulmonary resonance under the sternum in infants, and that in early life there is in the left chest behind and beneath the inner third of the clavicle a relatively dull area depending on the posterior position of the lungs and consequent proximity of the great vessels. In infants the writer percusses the relative dullness, the actual size of the heart, which is higher and more horizontal than in adults.

4. Beebe and Tracy investigated the action of the toxins of various bacteria on experimental lymphosarcomata in dogs. Suspensions of the B. prodigiosus seemed to have the most marked effect. Suspensions of the streptococcus pyogenes and the B. coli communis were also effective. Suspensions of staphylococcus pyogenes aureus and the soluble toxins of the B. prodigiosus had no effect on the tumors. The inoculations were given as a rule directly into one of the tumors. When any effect was observed, not only the tumor at the site of inoculation, but the other tumors diminished in size and finally apparently disappeared completely in a few months. [R. I. L.]

2. Lambert and Foster report 11 cases of benign stenosis of the pylorus in adults from various causes other than the scars of ulcers. In 6 cases the stenosis was due to increase in fibrous tissue, in 3 to adhesions about the pylorus, in 1 to pressure from enlarged abdominal glands, and in 1 to a myoma of the pylorus. These diagnoses were all based upon operative findings. Tests of gastric secretion gave results showing in some cases hyperacidity or hypersecretion, and in others achylia gastrica; it is inferred that excessive secretion is more common in earlier

cases and achylia in those of long standing. No mention is made of tests of motor function. In treatment, for cases of mild grade, medical measures may be given a trial, pyloric irritability being reduced by unstimulating diet: olive oil before meals and extract belladonna, gr. i, after meals, muscular activity being stimulated by extract of ergot, gr. i, after meals; electricity or systematic lavage, and secretion being decreased or stimulated according to the demands of the case by bismuth or oxide of magnesium and bland diet on the one hand, or by dilute mineral acids in frequent small doses, with stimulating diet on the other. But in all cases of any severity, resort should be had to surgery without undue delay. Of the 9 cases reported where results were known, 6 were cured and 2 partially cured; 1 case died of post-operative peritonitis.

4. Sewall and Childs call attention to the general failure of the medical practitioner to recognize aneurysm except in its late and unmanageable stages. As Osler has said, the symptom of pain is an early common manifestation, but even before this there may be pressure symptoms or signs, such as dyspnea, cough, hoarseness from laryngeal paralysis or diminution of breath sounds over one lobe of a lung. In any obscure disorder of the chest, especially where there is a history of syphilis, aneurysm should be thought of. The skiagram and fluoroscope should then be employed. But it must be remembered that by untrained observers aneurysm is frequently diagnosticated when it does not exist. The patient or screen may be improperly placed so as to give a distorted image; anomalies, tortuosities and dilatations of the aortic arch may occur; pulmonary vessels, bronchi and bronchial glands may cause confusion; pulmonary tuberculosis, pneumokoniosis and thickened pleura, especially the mediastinal pleura, may also give appearances which can be distinguished only with difficulty from aneurysm.

6. Eshner has made an exhaustive summary of the literature of diabetes in its relation to pregnancy. Much evidence exists of diminished power of assimilating carbohydrates in pregnancy. So marked is this that transitory glycosuria toward the end of pregnancy or during the puerperium may be considered physiological. True diabetes, however, as a complication of pregnancy is rare, since diabetes is less common in women than in men, since diabetes usually occurs later in life than the child-bearing period, and since diabetes as a rule inhibits conception. Yet a considerable number of cases are on record of pregnancy complicated by diabetes, and some cases are reported in which diabetes occurred in successive pregnancies. When diabetes and pregnancy coexist, the diabetes as a rule becomes worse and the pregnancy is seriously interfered with, the fetus often dying *in utero* or soon after delivery, and miscarriage or premature delivery being frequent. The child may be diabetic. Hydramnios is frequent. As an exception to the general rule that diabetes is aggravated by pregnancy, Eshner reports a case of diabetes in which the glycosuria disappeared with the inception of pregnancy and reappeared only after the delivery at about term of a macerated fetus. He finds no parallel case in the literature.

7. Elliott's article deals with those forms of thyroid toxemia which do not amount to true Graves's disease, but yet can be traced to morbid overactivity of the thyroid gland. Disorders due to such conditions Elliott believes to be more frequent than is recognized. He mentions a number of cases illustrating the types of symptoms which may be encountered, and the various predisposing circumstances upon which hyperthyroidism may supervene. The thyroid probably bears some functional relation to the organs of generation; disturbances in the sexual life of a patient may induce enlargement of the thyroid with temporary symptoms of thyroid intoxication. In some cases of simple goiter there are toxic outbursts manifested by nervousness, tremor and tachycardia. Heart disease, especially lesions of the mitral valve producing venous engorgement, is often the apparent cause of thyroid hyperactivity. Of great clinical interest is the association of hyperthyroidism with toxic conditions, digestive, uremic, or infectious. Tuberculosis is often accompanied by symptoms which suggest a thyroid source. More striking still, according to recent statistics, is the frequency with which hyperthyroidism or Graves's disease follows acute articular rheumatism and other acute infectious diseases.

8. *Berg, J. *On the Treatment of Ectopia Vesicæ.*

1. Clinical and laboratory study in Chicago seems to show that determination of the opsonic index is of occasional value in the diagnosis of obscure infections, and, combined with the use of bacterial vaccines, is of distinct value in the treatment of infections with the staphylococcus and of certain chronic localized forms of tuberculosis. Results are less definite in infections with the gonococcus and colon bacillus. In tuberculosis the combination of Bier treatment with vaccine therapy is found further to raise the opsonic index of fluids in the affected part. There are abundant charts, tables and case-reports and good descriptions of technic.

4. Appendicitis during the puerperium has been noted only in recent years. Hilton believes, but does not satisfactorily prove, that there is a direct causal relation, anatomic, physiologic, or mechanical, between the two. Certainly some of the cases cited represent pelvic abscess from neglected obstetric infection. Nevertheless, whether the relation be etiologic, secondary, or accidental, there is obvious importance in the prompt diagnosis and proper treatment of appendicitis coincident with the puerperium, when its recognition is especially difficult.

7. The report of eight highly successful cases of suprapubic prostatectomy raises the old question of the preferability of this method of operation to that by the perineal route. The most striking consideration in this series is the promptness with which the wound closes and normal micturition begins. Notable points in technic are early removal of suprapubic drainage and closure of the wound only at the upper angle, leaving at least half to granulate.

8. Berg describes his operation for extrophy of the bladder by bilateral iliac osteotomy with complete closure of the defect and his modification of Trendelenburg's method of ureteral implantation. He believes each operation has its peculiar advantages and indications. He further suggests an "ideal" operation combining the merits of both.

1. Wright and his fellow-workers present an interesting report of their work on the treatment of bacterial diseases by vaccines. The paper is divided into two parts; the first part treats of certain hitherto unregarded points in

connection with immunization curves obtained by bacterial inoculations. They then speak of auto-inoculations in very early tuberculosis, and show that there is an intimate relation between auto-inoculation and auto-immunization on the one hand, and the clinical symptoms of the patient on the other. They relate some very interesting effects of massage and of active muscular movements (including respiratory exercises) on the focus of infection, and incidentally on the opsonic index; the effect of operative interference on local foci and lastly the effect of active and passive hyperemia on these foci are discussed. They publish thirty-nine clinical records and opsonic charts. In part two they give the details of their methods of inducing auto-inoculations and the value of such methods in diagnosis and treatment. The paper shows evidence of careful, thorough, painstaking and yet very brilliant work. Their results certainly go to show that in an institute such as the one of which Wright is in control, where the opsonic index can be taken accurately by thoroughly trained workers, this method is of value to control the vaccine injections and in diagnosis. 9. JACOBJ, C. *To Economize the Use of Curare in Experiments on Frogs.*

1. Neisser in a short communication states that apes inoculated with syphilis do not develop the disease if they are treated with atoxyl. Large single doses are most effectual, and combination with trypan-red is better than atoxyl alone. Frambesia is also influenced by the drug, which makes a strong argument in favor of an etiological and clinical connection between the two diseases.

2. Bergell and Sticker mention the results that have already been obtained in cases of experimental new growths by injecting substances extracted from normal livers. In this way it has been possible to produce necrosis and liquefaction of carcinomas and sarcomas, and the theory has been suggested that the unrestrained growth of malignant neoplasms is due to absence or insufficient quantity of similar ferment-like bodies. So far, however, it has not been possible to produce the local effect without giving rise to toxic symptoms. In experiments on mice it was found impossible to cause complete disintegration of the tumor without endangering the life of the animal through toxic action of the organ extracts. In advanced experimental sarcomas in dogs, the authors had a similar experience. The injection of specific liver ferments caused regressive changes in the growth leading to its complete disappearance after it had reached a stage of development that excluded the possibility of spontaneous cure. The authors warn against a too sanguine attitude in regard to the application of the method to similar conditions in man, though they consider that the results obtained are of great theoretical value.

4. Franke remarks that 120 causes of heart injuries are on record in which operative treatment was attempted, with successful outcome in 46%. Fischer has collected 729 cases in which no operation was done, less than 16% surviving. After describing some personal experiences and discussing published reports, he agrees in the conclusion that the great danger in heart injuries is not from the injury itself, but from pressure on the organ by fluid accumulated in the pericardium. The first step must be to remove this pressure by puncture and aspiration, whether operation is contemplated or not. In most cases puncture will make the operation unnecessary. The general practitioner should aspirate when symptoms develop, without waiting for the surgeon. He quotes a Russian surgeon who has reported seven bullet wounds of the heart in Manchuria, in which complete recovery occurred under expectant treatment. Operations on the heart, even if successful, leave a predisposition to organic affections later, and the author therefore prefers early puncture of the pericardium. He punctures usually in the fifth interspace 2 or 3 cm. from the sternum, proceeding slowly and slanting the needle towards the median line. [L. G. M.]

1. Pässler and Seidel believe with Freund that the etiology of many cases of emphysema is to be found in a contraction and hardening of the cartilages of the ribs, with abolition of the movements of the thorax and resulting increase in its size, especially in the lower portions. The angle of Ludovic is much broadened. There is also a degeneration of the diaphragm. Freund has recommended in such cases the excision of parts of the rib cartilages, in this way bringing about a return of the respiratory movements of the thorax. The authors have tried this procedure in two cases, with improvement of symptoms in both. In such cases of emphysema the authors believe Freund's operation is of great value. The operation is indicated where there is dyspnea after slight exertion.

3. Bacmeister examined gallstones from twenty cases and found all but four sterile. In two of these cases the gallstones were of considerable standing, as evidenced by size and consistence of the stones and condition of the gall bladder. The stones contained typhoid bacilli, and there was a history of a comparatively recent typhoid infection. Working along these lines the author was able to cultivate typhoid bacilli from the center of fragments of sterile stones, which had been immersed in typhoid bouillon cultures. He concludes that it is possible for bacteria to pass into certain gallstones from the bile (especially cholesterin stones) or from the stones outward. [R. D.]

2. The authors describe a series of experiments in transplantation of epithelial tumors in mice. Successful transplantation was obtained in 201 individuals. An interesting observation was that the animals in which spontaneous resorption of the transplanted tumor occurred seemed to receive a specific immunity against this form of tumor, as no further attempt at transplantation was successful.

7. Spät holds that under certain conditions the influenza bacillus may have marked septic and pyogenic qualities. He reports a case of a young man who had bronchopneumonia and pleuritis followed by a general infection, ulcerative endocarditis and pyonephrosis, all due to the influenza bacillus.

8. Weigert claims that clinical and physiological observations and experiments show that there is a direct connection between the water content of the organism and its power of resistance against infection. The greater the fluid content, the less is the resisting power of the tissues. In animals fed on carbohydrates the fluid content is at its maximum. It is a demonstrable fact that different forms of food affect the composition of the organism. The author, working on these lines, fed five pigs on fat and five others on carbohydrates. The animals were then infected with tuberculosis, and it was found that the fat-fed pigs reacted in a much lesser degree to the infection than those fed on carbohydrates. Weigert suggests that, taking these results into consideration, the diet in human tuberculosis should be largely fat and should contain little carbohydrate food.

9. In an earlier work Westenhœffer showed that in the majority of cases of epidemic cerebrospinal meningitis, the nasopharynx, especially the pharyngeal tonsil, is the first focus of infection. According to observations carried out during the last epidemic in Germany, the schools are not places from which infection is spread, as the children do not spit out the infected sputum, but swallow it. In cases of pharyngeal infection, the spitting out of infected material would be of much importance in spreading the disease. The determination of a pharyngeal affection due to the diplococcus of Weichselbaum is important for the recognition of carriers of infection in the detection of the spread of the disease, and in the systematic prophylaxis against it. 4. Rostowzew, by the use of an enterotribe and the Paquelin cautery, has devised a method of intestinal suture, both end-to-end and lateral, by which he is able to make the anastomosis in an absolutely aseptic manner. He claims that the method is simple and that the operation time is shortened over that employed in other methods. Full illustrations are given in the text.

5. Klauber reports a case of a woman of thirty-six years who had had repeated severe attacks of gallstone colic for six months. At the end of this time there occurred fetid, purulent expectoration, which was soon followed by the expectoration of bile and pus. At operation the gall bladder was found enlarged and contained an encapsulated stone. The communication between the thoracic cavity and the biliary system could not definitely be made out, because of the poor condition of the patient. Its general situation, however, was the posterior surface of the liver and diaphragm. After drainage of the gall bladder, convalescence was uncomplicated, there being no further expectoration of bile.

6. In the diagnosis of Hirschsprung's disease, Neugebauer uses a rectal sound and the x-ray. In each of the two instances which he reports, the x-ray picture showed the shadow of the sound somewhat to the left of the navel going upward toward the right, even as far as the fourth rib, and then bending toward the left. The first case reported was that of a nine-months-old child in which the autopsy confirmed the diagnosis of dilatation of the colon. The second instance was in a boy of twelve, who was completely cured by a large-sized lateral anastomosis between the beginning of the transverse colon and the lower end of the sigmoid. In this second case, in spite of the fact that the bowels moved voluntarily after operation, an examination a year later showed that the sigmoid was still abnormally enlarged, and that the high positions of the diaphragm and liver were still present. For these reasons Neugebauer considers the disease to be congenital, at least in its inception. In neither of his two cases was he able to demonstrate any valvular closure of the gut.

9. Following a gastrostomy, through which the patient was fed, Rokitzky made a plastic operation on the esophagus for stricture, by turning in a flap of skin from the front of the neck, after excision of the cicatricial portion of the esophagus. This flap was sutured over a tube. Four months later the esophagoscope showed perfect union, with some dilatation at the point of suture. The final result was most excellent; all forms of food could be swallowed and the dilatation only made itself evident as a scarcely visible swelling which appeared at the site of operation during swallowing. [W. C. Q.]

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED NOV. 20, 1907.

BAILHACHE, P. H., surgeon. Granted leave of absence for 7 days from Nov. 20, 1907, under paragraph 189, Service regulations.

CARRINGTON, P. M., surgeon. Granted leave of absence for 6 days from Nov. 16, 1907, under paragraph 189, Service regulations.

CARRINGTON, P. M., surgeon. Granted 2 days' extension leave of absence from Nov. 22, 1907. Nov. 20, 1907.

MCINTOSH, W. P., surgeon. Granted leave of absence for 10 days from Nov. 27, 1907. Nov. 14, 1907.

VON EZDORF, R. H., passed assistant surgeon. Detailed as a delegate to the Third International Sanitary Convention, to be held in the City of Mexico, Dec. 2–7, 1907; upon completion of which duty to rejoin his station at New Orleans Quarantine. Nov. 13, 1907.

ANDERSON, J. F., passed assistant surgeon. Detailed to represent the Service at the meeting of the American Association for the Advancement of Science, to be held in Chicago, Ill., Dec. 29, 1907; upon completion of which to rejoin his station at Washington, D. C. Nov. 13, 1907.

ANDERSON, J. F., passed assistant surgeon. Granted leave of absence for 7 days from Nov. 14, 1907, under paragraph 191, Service regulations.

ANDERSON, J. F., passed assistant surgeon. Granted 6 days' extension leave of absence from Nov. 21, 1907. Nov. 16, 1907.

HOLT, J. M., passed assistant surgeon. Leave of absence granted Passed Assistant-Surgeon Holt for 23 days from Sept. 7, 1907, revoked. Nov. 14, 1907.

BOGGESS, J. S., passed assistant surgeon. Relieved from duty at Quebec, Canada, and directed to proceed to St. John, N. B., for duty. Nov. 16, 1907.

SPRATT, R. D., assistant surgeon. Granted leave of absence for 1 month from Dec. 12, 1907. Nov. 20, 1907.

BRYAN, W. M., assistant surgeon. Directed to proceed to Savannah Quarantine Station for temporary duty: upon completion of which to rejoin his station at New Orleans, La. Nov. 18, 1907.

GILL, S. G., acting assistant surgeon. Granted leave of absence for 30 days from Dec. 4, 1907. Nov. 15, 1907.

GREGORY, G. A., acting assistant surgeon. Granted leave of absence for 14 days from Nov. 14, 1907. Nov. 16, 1907.

STEARNS, H. H., acting assistant surgeon. Granted leave of absence for 2 days from Nov. 10, 1907, on account of sickness. Nov. 18, 1907.

LAGRANGE, J. V., pharmacist. Granted leave of absence for 7 days from Nov. 14, 1907, under paragraph 210, Service regulations.

HEPLER, G. K., pharmacist. Relieved from duty at Chicago, Ill., and directed to proceed to Louisville, Ky., reporting to the medical officer in command for duty and assignment to quarters. Nov. 16, 1907.

RESIGNATION.

PHARMACIST L. P. HALL resigned to take effect Nov. 2, 1907.

BOARD CONVENED.

A board of medical officers was convened to meet at Boston, Mass., Nov. 20, 1907, for the purpose of conducting a physical examination of an officer of the Revenue-Cutter Service. Detail for the board: Surgeon R. M. Woodward, chairman; and Assistant Surgeon T. W. Salmon, recorder. Nov. 18, 1907.

SOCIETY NOTICES.

BOSTON MEDICAL LIBRARY. — The Boston Medical Library is open five evenings in every week until 10 P. M. from Nov. 1 to June 1, being closed only Saturday and Sunday evenings. There seems to be a certain amount of misapprehension on this point and the notice on the Library front door is not seen by all the members.

W. L. BURRAGE, M.D.,
Chairman, House Committee.

THE HOSPITAL CONFERENCE OF THE CITY OF NEW YORK. — A special meeting of the Hospital Conference will be held at St. Luke's Hospital, Cathedral Heights, on Friday evening, Nov. 29, 1907, at 8.30 o'clock, to consider the adoption of recommendations to be submitted by the Committee on Ambulance Service, relating to the ambulance service of Greater New York. The Committee on Ambulance Service will ask that its recommendations, or such other recommendations as may be adopted, be laid before the Mayor's Hospital Commission.

GEORGE F. CLOVER, *President.* S. S. GOLDWATER, *Secretary.*

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. — The annual meeting will be held at the St. Charles Hotel, New Orleans, La., the 17th, 18th and 19th of December, 1907.

DENEGRE MARTIN, M.D.,
Chairman, Committee of Arrangements.

A PROPOSED NEW ENGLAND PEDIATRIC SOCIETY. — The Visiting Staff of the Boston Floating Hospital request all those interested in the formation of a New England Pediatric Society to meet at the Boston Medical Library, 8, The Fenway, Saturday, Jan. 4, 1908, at 8.15 P. M. It is hoped that this movement will excite general interest and that the attendance at the meeting will not be limited to those working along this special line.

JOHN LOVETT MORSE, *Chairman.*
WILLIAM E. FAY,
ARTHUR WILLARD FAIRBANKS,
CHARLES W. TOWNSEND,
HENRY I. BOWDITCH, *Secretary.*

RECENT DEATHS.

DR. AARON DAVIDOW, of New York, who was graduated at Chicago in 1894, died on Nov. 18.

DR. WILLIAM NATHAN BELCHER, a prominent physician of Brooklyn, N. Y., died on Nov. 20. He was born in Brooklyn in 1862, and was graduated from the Long Island College Hospital in 1884. Among the positions that he held were those of attending physician to the Long Island College Hospital, the Polhemus Memorial Clinic and the Methodist Episcopal (Seney) Hospital, and pathologist to St. Christopher's Hospital, Brooklyn.

THE TECHNIC TO BE OBSERVED IN THE EXAMINATION AND LOCAL TREATMENT OF THE UPPER RECTUM AND PELVIC COLON.

BY T. CHITTENDEN HILL, M.D.,
Surgeon to the Rectal Department of the Boston Dispensary, Boston.

At the present time there exists in the profession a general manifestation of interest and realization of the important bearing that certain local lesions and structural changes, brought about by catarrhal and inflammatory conditions of the rectum and sigmoid, may have as etiological factors in the causation of chronic constipation, chronic diarrhea, so-called mucous colitis, ulcerative colitis, reflex symptoms of both the male and female genito-urinary organs, as well as various aches and pains of the rectal, sacral and lumbar regions.

The reason for this aroused interest in old subjects may be attributed to the rather recent discovery that the upper rectum and pelvic colon can be thoroughly explored and many localized inflammatory processes treated, and even operative procedures carried out through the electrically lighted sigmoidoscope.

A number of original workers, both in this country and abroad, have during the past four or five years thrown much light on some of these obscure disorders, at the same time suggesting more rational methods of treatment.

While recognizing the fact that it may properly be said that the whole subject is in a sense in an evolutionary stage of development, yet the first principles and primary general truths have been studied, their importance recognized and established beyond a question of doubt.

Thus our knowledge of these conditions which have necessarily been founded chiefly on the symptoms which they produce, and a physical examination, such as abdominal palpation or at most the examination of the feces are, at the present time, supplemented and simplified by direct instrumental examination of the bowel.

The result has been that our views have been considerably altered as to the pathology of the diseases just mentioned, and altogether different methods of treatment have suggested themselves.

The sigmoidoscope has been to the writer a very necessary adjunct in his efforts to accurately diagnose and treat some of the more difficult of these cases. Inasmuch as even recent graduates of our best medical schools receive but little instruction in this important domain of surgery, a description of the technic employed and certain practical suggestions may be of interest to some who have not had the opportunity for studying the diseases of the lower portion of the bowel. The qualified graduate of to-day has prepared for the practice of medicine by attending special clinics where he has been afforded an opportunity to gain a general knowledge of nearly every department of medicine and surgery, with the notable exception of diseases common to the rectum and sigmoid.

Such being the case it is scarcely to be wondered at that many otherwise skillful practitioners imagine great difficulties to surround the correct diagnosis of these cases, and more often than otherwise the treatment undertaken is entirely of a perfunctory and haphazard nature.

The remarks that follow are not intended to convey the impression that every patient applying for treatment for constipation, diarrhea or mucous colitis should at once be put to the inconvenience of a sigmoidoscopic examination.

Nevertheless, I am convinced that a systematic examination of some of the more obstinate of these cases, not benefited by intelligent medical treatment, would disclose definite lesions, or at least inflammatory conditions of the mucous membrane of the rectum or sigmoid which must be corrected before any other treatment will be of much avail.

PREPARATION OF THE PATIENT FOR EXAMINATION.

Inasmuch as rectal examinations are distasteful to many, and for the further reason that many patients are imbued with the impression that instrumental examinations of this region of the body are particularly painful, I shall give much attention to details, the description of which it is hoped will not prove tiresome.

With the patient properly prepared there is nothing about a rectal examination that is any more disagreeable than an exploration of any of the cavities of the body, and when dexterously conducted it should not cause any more discomfort. Save in exceptional instances any table, such as is procurable in the ordinary household, will serve for a satisfactory examination. The elbows and knees for male patients, and the right lateral semi-prone for women are the easiest positions in which to conduct the preliminary examination.

In the first position the whole peri-anal region is readily accessible without the aid of an assistant, while in the latter the patient, if an assistant is not at hand, can facilitate the examination by supporting the left buttock.

The sweat and sebaceous glands in the immediate vicinity of the anus are numerous and large, and for this reason the anal orifice should be cleansed by thoroughly wiping with absorbent cotton, which has been wrung dry of some antiseptic solution. After carefully inspecting and palpating all about the anus, the index finger with soap under the nail (if gloves are not used) is smeared with a stiff lubricant, and gently inserted with a rotary motion into the rectum. It is unnecessary to soil the finger with fecal material as its presence should be noted before actual contact takes place. When the rectum is found to contain feces, a small enema of boric acid solution, not exceeding ten ounces, will quickly empty the rectum and likewise the sigmoid in many instances, in such a manner as to permit of instrumental examination. The small enema will almost invariably answer for exploration of the rectum itself, but in atonic conditions of the large intestine it will be found necessary

to ask the patient to call later and be prepared as follows: on the morning preceding the day set for examination, 3 to 6 dr. of magnesium sulphate or a suitable dose of some saline mineral water should be taken.

Three hours before coming to the office, the bowel is further cleansed with a large enema of normal saline solution taken in the knee-chest posture, followed two hours later by the injection of half a pint of clear water containing an ounce of glycerin. This last enema should never exceed the amount stipulated, for if larger some may remain in the sigmoid and cause much annoyance by being discharged during the examination or treatment.

TECHNIC OF PASSING THE TUBE.

It is difficult to formulate definite rules as to the technic of exploring the sigmoid. It is easier and much more satisfactory to demonstrate to the beginner the principles involved than to describe it, and then with a little practice any one who has had previous experience in the use of similar instruments, can accustom one's self to passing the tube in a manner that will be entirely safe and satisfactory to both patient and surgeon.

It is readily apparent to all, that the greatest care and caution should be exercised in passing the sigmoidoscope, especially when there is an active ulcerative condition of the bowel, or other inflammatory condition of the neighboring organs. A case[1] has recently been reported by G. Sultan in which perforation of the rectum near the recto-sigmoidal juncture took place during a sigmoido-scopic examination. The patient, a woman aged fifty-three, was suffering from chronic catarrh of the large intestine. The instrument was readily passed for 20 cm. At this point distention with air was begun. During the distention the patient complained suddenly of great distress, and at the same moment Sultan could see in the sigmoidoscope the serous membrane right before him bulging into the rectum. He describes in much detail the repair of the injury. Immediate laparotomy — suturing the rent and the finding of a particle of fecal matter the size of a cherry in the lower true pelvis. The patient died seven weeks later, and in the depth of the abdomen was found an encapsulated abscess.

Notwithstanding this unfortunate experience he concludes his paper with the statement "that in the rectoscope we have a distinct aid which is not possible in any other manner or method in forming a decision concerning changes in the rectum or sigmoid. We must, however, always bear in mind how dangerous this instrument can be of which we make use."

There are reported instances in which rough handling and undue force in passing the tube has been followed by perforation of the bowel, and the instrument has passed on into the peritoneal cavity.

Such methods, however, are absolutely unjustifiable, and if the rule is followed to use no force after the end of the sigmoidoscope has passed the anal sphincters no such serious complications can possibly arise.

Before introducing the tube the patient should be made as comfortable as possible in the genu-pectoral position.

If for some reason this posture is impossible because of an anchylosed or amputated lower extremity or great discomfort of assuming this position, the lateral semi-prone with the knees well drawn up on the abdomen may be substituted.

In fact, this latter position is favored by some proctologists for asthetic reasons, claiming that it is much pleasanter for women and hypersensitive individuals, but the writer believes that the greater ease with which the instrument is passed and so much less discomfort is occasioned the patient that the genu-pectoral position should nearly always be the one of preference.

The passage of any instrument into the rectum is rendered less difficult by first inserting the finger past the sphincters. This procedure dilates and lubricates the anal canal, as well as affords the surgeon opportunity to ascertain the exact direction in which the instrument should be guided before the obturator is withdrawn.

The sigmoidoscope, warm and smeared with vaseline, should be pressed firmly over the anal orifice, the patient at the same time being requested to strain down, thus relaxing the sphincters. Steady firm pressure, in a downward and forward direction, should be made on the handle of the instrument until it has passed the anal canal. After this portion has been passed, the handle should first be gradually lowered and pushed forward until the end of the instrument has reached the middle portion of the sacrum. At this point the obturator should be withdrawn, which will allow the bowel to become distended with air so that the tube can be passed onward by sight. The instrument is then gradually raised, allowing it to be gently pushed onward to the promontory of the sacrum, where considerable resistance to the onward progress of the instrument is met with. A great deal of difficulty is experienced by the beginner in passing the instrument into the sigmoid, because of a well developed fold of mucous membrane, known as O'Beirne's sphincter, situated at the junction of the sigmoid and rectum. This valve-like sphincter frequently makes the rectum appear to end abruptly in a blind pocket. If careful search now be made, the valve will be located in close apposition to the opposite wall of the gut. It can then be effaced with the end of the instrument so as not to retard its further progress into the sigmoid flexure. From now on the directions usually given are to make slight pressure on the hand bulb of the pneumatic sigmoidoscope which will sufficiently inflate the gut so that it may be inserted to its full extent, and the whole interior of this portion of the intestine brought plainly into view. During the past year I have practically discarded the hand bulb as I have found that by placing the patient in a good proctoscopic position it is rarely required. Its use is

[1] Deut. Zeitschr. für Chir., p. 397.

often very distressing and in ulcerative conditions it must be regarded as a dangerous practice. In some cases an invagination, acute flexure, sacculation, or narrowing of the caliber of the gut will not be straightened out by air insufflation. Air will pass through such places causing considerable distention without one's being aware of it, unless the patient complains of abdominal pain. It is in such cases as these when there is ulceration above that the greatest danger lies.

If the onward progress of the instrument is impeded it is better to slightly withdraw the instrument, get the direction of the gut and reinsert the obturator which will allow the tube to be passed with less inconvenience to the patient. This maneuver can be repeated until the tube has been passed as far as desired.

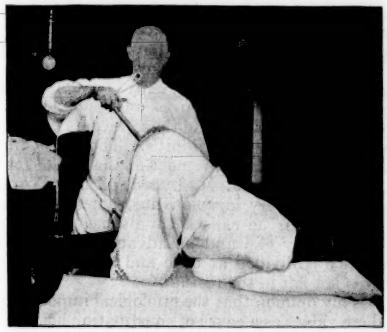

Fig. 1. Relative direction of the tube when passing the sphincters.

The photographs here reproduced are intended to give in a general way the relative direction of the tube: when passing the sphincters (Fig. 1),

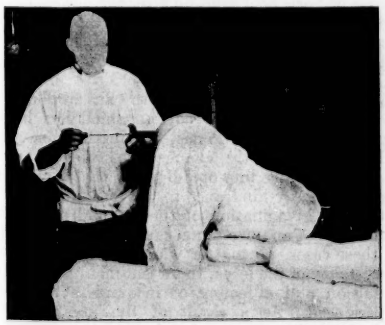

Fig. 2. The end of the tube has reached the middle portion of the sacrum. The obturator should be withdrawn at this point.

when it has reached the middle portion of the sacrum (Fig. 2), its passage over the promontory of the sacrum (Fig. 3), and when inside the pelvic colon (Fig. 4). The great majority of sigmoidoscopic examinations are conducted without the use of general anesthesia. Occasionally, however, it is desirable when there are painful affections about the anus, or the patient is apprehensive of being hurt. It should always be borne in mind when employing ether that there is much more danger of injury to the intestine as we do not have the patient's sensations to warn us when making too much pressure or distention.

Fig. 3. Passing the tube over the promontory of the sacrum.

We have, therefore, in the sigmoidoscope an instrument of precision which should be resorted to in the treatment of many conditions which are dependent on catarrhal inflammations of the rectum or pelvic colon, such as hypertrophic and atrophic catarrh, traumatic, tubercular and

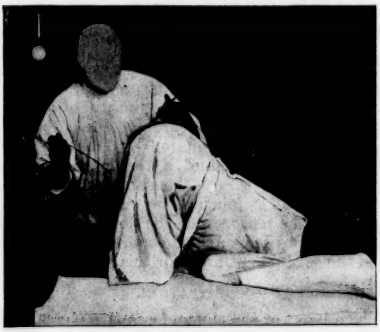

Fig. 4. The tube inside the pelvic colon.

specific ulceration, etc. With the lesions brought plainly into view and easy of reach, direct topical applications to the diseased tissues may be made which will prove more effective than the more commonly employed medicated enemas and suppositories.

CHRONIC DIARRHEA.

Cases of chronic diarrhea that have resisted careful medical treatment are often caused by circumscribed ulcerated areas of the rectum or

sigmoid which are readily accessible through the sigmoidoscope.

Through the courtesy of different members of the Medical Staff of the Boston Dispensary, I have had an opportunity of examining and treating many such cases, and frequently lesions have been discovered that yielded very promptly to local treatment.

The plan of treatment carried out was briefly as follows: The restriction of the diet to non-irritating foods such as milk, soft boiled eggs, gruels, boiled rice, nourishing soups, etc., as well as the avoidance of cold, acid or alcoholic beverages, greasy and highly seasoned foods and excesses of tea or coffee.

The local treatment mainly relied upon was high colonic flushings with boric acid or normal salt solution, together with the topical use of nitrate of silver, from one to two drams to the ounce, to all abrasions or ulcerations present. In some cases instead of the silver solution, ichthyol in glycerin 15%, or balsam of Peru in castor oil 15%, seemed to act with better results. Those cases in which there are reasons to believe that pathological lesions exist above the pelvic colon may be treated by medicated emulsions of olive oil through a long colon tube.

The thorough flushing of the colon is very soothing and healing to an inflamed and ulcerated mucosa, and when supplemented with the above and topical applications, much can be done to check the copious and frequent diarrheal discharges. A diarrhea dependent upon a localized or general enteritis of course would not be benefited by local treatment, but many of these cases are well of the disease of the small intestine, yet there remains the ulcerated or inflamed condition of the colon or rectum.

Cases of ulcerative colo-proctitis, especially if of a syphilitic or dysenteric nature, which prove obstinate to treatment per rectum will often yield readily to colon flushing through the appendix. The operation was originated by Dr. Robert F. Weir, of New York, and if the appendix is of sufficient caliber serves the same purpose as a cecostomy and is much more agreeable to the patient for the reason that the former operation does not allow the escape of feces as often happens when the cecum is utilized for this purpose.

CONSTIPATION.

The advent of the sigmoidoscope gave a fresh impetus to the study of constipation, as it was very interesting to note in what particulars the rectum and sigmoid of a patient who habitually carried about a load of fecal material in these organs, varied from the normal. The subject of constipation is a large one involving the chemistry of digestion, dietetics, etc., as well as mechanical obstructions and inflammatory conditions of the abdominal organs. Leaving all these general and complex questions, I will mention briefly the treatment of certain conditions that are frequently met with in the terminal portion of the digestive tract.

In all cases, the usual routine of regular time of going to stool, the correction of errors of diet, eating plenty of fruit and drinking an abundance of water, out-of-door exercise, gymnastics, etc., when possible should be insisted upon. Abdominal massage and kneading of the colon is often a valuable adjunct to other treatment.

The valves of Houston congenitally enlarged or hypertrophied and stiffened, as a result of catarrhal inflammation, may be the cause of constipation. Dr. T. C. Martin, of Washington, was the first to recognize this fact and recommend the operation of valvotomy for its relief.

Dr. Martin's operation consisted in incising through the proctoscope the valve or valves and suturing the free border, which operation he still advocates. The procedure, however, except in skilled hands, may be attended with hemorrhage or fatal puncture of the bowel. Various automatic valve clips have been made which serve the same purpose by dividing the valves by pressure necrosis, and when these are used there is no danger of hemorrhage or perforation. Should the peritoneum by any possibility be included in the valve it causes adhesions to form between the two layers and thus prevents perforation and subsequent peritonitis. The clips come away with the fecal movement at the end of four or five days. Dr. J. M. Lynch, of New York, has devised a very ingenious instrument for this purpose, which he calls a thyrotome. It is an electro-cautery clip and its advantages are that the valve is divided at once and thus a foreign body is not left in the rectum.

It is my opinion that the etiological importance of these valves as a cause of constipation has been somewhat overestimated, but occasional cases will be met with where the valves form an obstruction which can be dealt with in no other way. I believe it is always better to try a palliative course of treatment before division. Emptying of the rectum of any retained feces by an 8-oz. enema of boric acid solution after the bowels have moved in the morning will improve the catarrhal condition which is always present in these overloaded recti. Two or three times a week the valves should be massaged for five minutes through the proctoscope with an applicator protected by absorbent cotton which has been dipped in olive oil. Persistence in this massage will very frequently change a stiffened and obstructing valve into one so pliant that it cannot possibly be any hindrance to the fecal current.

Chronic invagination of the sigmoid or upper rectum is not an uncommon cause of constipation. In these cases, no matter what the character or consistency of the feces, there is difficulty in their expulsion and a feeling of incomplete relief is experienced. As a result of the invagination superficial ulceration of the sigmoidal and rectal mucosa is soon produced, and this may be manifested by the discharge of mucus sometimes streaked with blood and pus. By careful digital examination one may feel the invaginating sigmoid, and through the proctoscope it may be seen as the patient strains down.

The treatment may be either palliative or opera-

tive. The palliative will sometimes prove successful, and consists in replacement by air dilatation with the pneumatic proctoscope with the patient in the knee-chest position. After such replacement of the gut the bowels will sometimes act regularly for a few days, and persistence in this line of treatment may effect a cure. At the same time ulcerations present are treated by direct topical applications. Should palliative measures prove of no avail the suturing of the sigmoid to the abdominal wall (sigmoidopexy) will prevent the invagination.

Stricture of the rectum should not be forgotten in this connection. I have seen several cases that had received prolonged medicinal treatment without the real cause being ascertained. In two cases the stricture was annular and situated just within the internal sphincter and barely admitted the examining finger.

Hypertrophy and spasm of the external sphincter muscle is a more common cause of constipation than is generally supposed. In these cases usually a small ulcer will be found somewhere in the anal canal, which is irritated by the fecal discharges and thus keeps up the spasm and rigidity of the muscle. The treatment for this condition is the same as that for anal fissure.

RECTAL CANCER.

Notwithstanding the accuracy with which rectal cancer can now be diagnosed, it is a fact, most surgeons will agree to, that an early diagnosis is made out in only a small percentage of the patients that present themselves for operation. Perhaps not more than one fifth of the cases are suitable for radical operation, yet these growths of the lower rectum can be easily recognized by digital examination alone, while those of the upper rectum and pelvic colon can nearly always be accurately located with the sigmoidoscope. Should there be doubt as to the nature of the neoplasm it can be differentiated from other tumors by removing a portion for microscopical examination.

In the early stages when the growth is small bi-manual palpation is unreliable. Exploratory incision is probably the surest method of making the diagnosis, but it is only infrequently that such an operation is necessary. Cancer of the large intestine will continue to be overlooked until we, as a profession, recognize how frequently it occurs (according to late statistics three quarters of the malignant growths of the intestinal tract are located in the rectum or sigmoid) and become more discerning as to the initial symptoms of this insidious disease. It can readily be perceived that the general practitioner will frequently overlook the first vague symptoms of malignant disease of the rectum.

It is a common experience to hear these patients remark that for six months or a year previously they had consulted their physician for certain unusual sensations in the rectum, such as a feeling of weight and fullness that was only relieved by defecation; or a patient who has heretofore been regular in his habits may have complained of a gradually increasing constipation, which is a very suggestive, early symptom of malignant disease of the rectum. Even after the cardinal symptoms, such as muco-purulent or bloody stools, constipation alternating with diarrhea, etc., appear, the diagnosis may have been obscured by complications such as piles, fistula or ulceration, for such patients often appear vigorous and robust for a long time, since the neoplasm is situated at the lower end of the digestive tract and thus has not interfered in any way with the digestion and assimilation of nourishment.

Many patients have been seen by the writer, illustrating how far advanced these cases often get, before they are discovered, and not until we, as physicians, make it a routine practice to examine every patient with however indefinite rectal symptoms, by means of the newer and more modern instruments at our disposal, will the mortality of rectal cancer be materially reduced.

SOME FURTHER STUDIES ON NOCTURNAL PARALYSIS.

BY ISADOR H. CORIAT, M.D.,
Second Assistant Physician for Diseases of the Nervous System, Boston City Hospital.

(From the Neurological Clinic of the Boston City Hospital.)

IN a recent contribution upon this subject,[1] I reported the case of a woman, in whom, following a distressing emotional shock, there developed a peculiar symptom-complex. In the half-waking and half-sleeping condition (hypnagogic state), there arose a state of general palsy, which, in its clinical picture, was an exact motor repetition of the original emotional episode. The disorder was interpreted as a functional dissociation and closely related to the temporary, general palsy that is sometimes observed in patients who are suddenly awakened from a deep hypnosis. Complete recovery took place by psychotherapeutic methods. Since reporting this case, four others of a similar nature have been observed. These have not only helped to clear the clinical aspects of the question, but have thrown considerable light on the origin and evolution of the attacks. Furthermore, a search through the literature has brought several similar contributions to light, which may be added to the papers by Weir Mitchell and Ch. Féré, already quoted.

Bleuler,[2] in a subjective analysis of his sensations while hypnotized, experienced a partial palsy on awakening from the state of autohypnosis. In a discussion of the variants of dream consciousness, Jastrow [3] seems to have had this condition of general nocturnal palsy in mind. He writes: "It may be pertinent to note that there seems occasionally a condition of dream stupor that may be induced in predisposed sleepers by sudden awakening, though it also occurs spontaneously. The subject thereof finds

great difficulty in regaining consciousness, as also getting control of muscles and sense organs. He may 'reel and stagger, rub his eyes and make efforts to keep them open, apparently struggling against a relapse into deeper sleep; and somewhat dazed and befogged in his perceptions, his condition suggests the intoxication through the action of a drug. At times also he proves to be suggestible and able to perform routine actions in an automatic fashion. An energetic stimulus, such as a dash of water upon his face, may be needed to arouse his dormant faculties."

In a recent contribution, Gudden [4] applies the term "sleep drunkness" to the state of an individual, in whom the transition from the sleeping to the waking state is slow and there is a delay in the return of grasp of environment and of capacity for action. The individual is in a half-dream state and the real world is only hazily grasped. In his group I, called by him physiological "sleep drunkness," he speaks of the temporary inability to move or talk, although the mental grasp may be quite clear. Both Krafft-Ebing and Pfister apply the term to that half-waking and half-sleeping state in which the psychomotor activity is altered. The individual cannot speak, is rigid, numb, unable to move, although he appears to possess a complete consciousness. All these observations appear to correspond to the nocturnal palsy of our cases, except here that the consciousness seems rather hazy and bears a direct relation to the feeling of inability to move. As will be shown later, however, the phenomenon bears no relation to sudden awakening.

Furthermore our studies have shown that the symptom-complex is merely a portion of the clinical picture of a neurasthenic or psychasthenic neurosis, hysteria or a recurrent mental state. The following three cases are from the service of Dr. Thomas:

CASE I. PSYCHASTHENIA WITH PECULIAR CRISES AND NOCTURNAL PALSY.

The patient, H. O., age thirty-eight, first came to the Neurological Clinic on June 5, 1907. She was perfectly healthy up to the age of twenty-six, when, following an attack of typhoid fever, she became nervous and depressed for a time and had a fear of death. She recovered, however, and has remained well since, up to the onset of her present trouble. The patient came to the clinic complaining of ordinary neurasthenic symptoms, but on closer analysis the following symptom-complex was elicited. During the first week of May, 1907, her husband went to California in order to better his financial condition. She worried considerably over this and finally went into a state of great anxiety, more particularly because she had received no letters from her husband for three weeks. At this time also her son became ill and this in a measure added to the anxious mental condition. When the assuring letter finally did arrive, the anxiety failed to improve and she began to fear the journey to California and its consequent breaking up of her home in Boston. During the day she became quite irritable, started at slight sounds, sleep was poor, but without any specially distressing dreams; there developed a premonition of something terrible about to happen, that her husband was dead, that her child might die, etc. The feeling of anxiety was associated with numb sensations mounting from her feet to her head; there was occasional vertigo; an almost constant feeling of physical weakness, and there finally developed a frequent diarrhea. At the height of the episodes of anxiety and fear there supervened a peculiar mental state almost resembling a psycholeptic crisis. There was no sensation of a blow on the head, but "a blur comes before my eyes, things are getting dimmer," "things seem to be fading away," etc. These sensations, however, never reached an actual sense of unreality.

Parallel with these episodes of anxiety, there arose the nocturnal palsy. Three or four times during the night she would awaken from her sleep and in the half-waking and half-drowsy hypnagogic state would experience a sudden jerky sensation, followed by an inability to move the limbs. The total inability to move would last for three or four minutes, and there was a general sensation of numbness in the limbs. At first all her will power would not serve to move her body, but finally, after a few minutes of exercising her strongest will, she would be able to throw the limbs about, but even then with considerable difficulty on account of the subjective feeling of numbness. During the few minutes that this general palsy persisted the limbs feel paralyzed and "like withered," the heart palpitates, the eyes are wide open and there is a sense of intense fear and impending death. The attacks are worse in the early morning, about 5 A.M. During the attacks, she is always clearly oriented and there is no amnesia or haziness of memory for the individual attacks. This nocturnal palsy has always occurred in the half-waking and half-sleeping hypnagogic state, and as the patient became more fully awakened, the paralysis gradually grew less and she was able to move the limbs. At no time has the palsy persisted after the patient has become fully awake. These attacks have occurred every night up to the present. The physical examination was negative with the exception of a fine tremor of the tongue, lips and outstretched hands. Nothing special was elicited in abstraction.

Here we seem to be dealing with a psychasthenic neurosis associated with frequent diurnal crises of anxiety and nocturnal palsy. This latter can be best interpreted as an equivalent of the daily crises, both being due to an interference with the normal psychological tension and leading to a dissociation of consciousness. Janet in his voluminous treatise makes no mention of this particular disorder of sleep as an equivalent of the psychasthenic crises. The treatment in this case consisted of waking suggestions directed towards the cessation of the crises and the nocturnal palsy. The psychotherapeutic technic was identical with that employed in the case cited in my first paper. As a result, the patient completely recovered in the course of a few weeks and was able to journey and join her husband in California.

CASE II. NEURASTHENIA WITH RATHER PROTRACTED ATTACKS OF NOCTURNAL PALSY.

A. G., age twenty, came to the Neurological Clinic on Aug. 23, 1907, complaining of neurasthenic symptoms. She always enjoyed good health up to within two months. Since this time, however, she has been sleepless at night; during the day, she has been restless and fidgety, would drop objects, worried over trifles, and has noticed frequent precordial palpitation. There was no

[4] H. Gudden: Die physiologische und pathologische Schlaftrunkenheit. Archiv. für Psychiat., Bd. 40, H. 3, 1905.

sense of exhaustion and no headache. The physical examination was negative. During the period of her neurasthenic symptoms, she has been subject to attacks of nocturnal paralysis occurring two or three times a week. She will awaken during the night in a state of moderate fear and although she feels fully conscious, yet finds it impossible to move her limbs or body or even to cry out, for a period of fifteen minutes for each attack. She is certain that the individual attacks last fully fifteen minutes, because she is in the habit of hanging her watch at the head of the bed, the eyes are open in the attacks and she is thus able to time herself, although unable to move a muscle. Usually the hands are clasped at the back of the head and she is unable to pull them from under her. On the morning following an attack, there is a feeling of weakness in the arms and legs, but no tingling. These phenomena of nocturnal palsy, as in the previous case, always occurred in the half-waking and half-sleeping condition; the eyes were wide open, but try as she would, she was totally unable to move or to cry out. As there was a transition from this hypnagogic state to a complete waking condition, the general palsy gradually wore off, at first the arms could be pulled down and then she was able to move the limbs.

If the histological theory of sleep were substantiated by sound experiment, this case would offer a fascinating opportunity to conclude that the dendrites were still in a state of retraction. Psychotherapeutic procedures were used in this case; the attacks ceased during the first week of treatment, after which the patient failed to come to the clinic, so that the ultimate result is unknown.

CASE III. HYSTERIA WITH NARCOLEPTIC ATTACKS AND NOCTURNAL PALSY.

C. M., age forty-five, first presented herself to the Neurological Clinic on July 26, 1907. She never suffered from any serious illness, neither was there any history of narcoleptic attacks in the immediate family or its collateral branches. For eight years she has suffered from peculiar attacks consisting of an irresistible impulse to sleep. These would occur a number of times during the day, particularly when she sat down or was engaged in sewing or reading. At times she would be compelled to bite the tongue in order to keep awake. These narcoleptic attacks would last only a few minutes at a time and were usually preceded by slight vertigo. It was impossible to trace the origin of the attacks. They continued without interruption for six months, then ceased and did not return until the spring of 1907, when they again became of almost daily occurrence. Five years ago, there was an attack of aphonia lasting six weeks, and at present there is almost a constant sensation of a "globe" in the throat. On several occasions, particularly when excited, vision has been suddenly lost. At no time has there been any headache, vomiting or paralyses. About four years ago, she began to suffer from attacks of nocturnal paralysis. She would awaken from a sound sleep and while in the half-sleepy (hypnagogic) state, would find herself unable to open her eyes or move her limbs. This motor paralysis would last for a few minutes only, and as she became fully awake power would return. At no time was she able to come out of the individual attacks voluntarily while in the half-sleepy condition, but always could do so, as she became more fully awake. Sometimes she would be awakened by the crying of one of her children, but even under these circumstances would find herself unable to stir. The day following the attacks, she suffered from pain in the arms and fingers. These attacks of nocturnal paralysis occurred every night for about six months, then ceased, but have recently returned, but to a slighter degree. Nothing was obtained in experimental distraction, neither were there any physical stigmata of hysteria. As in the other cases the treatment was waking suggestion directed against the narcoleptic attacks and nocturnal palsy given three times a week, with the result that continued improvement took place during the first month, after which both types of attacks ceased altogether. The effect of psychotherapy in this case is of some interest. Not only did the nocturnal palsy completely cease, but in addition the patient recovered from the narcoleptic attacks. In Camp's recent case of narcolepsy,[5] suggestion brought about a cure, after the administration of caffeine had completely failed to keep the patient awake.

CASE IV. (Service of Dr. Prince).

NEURASTHENIA WITH NOCTURNAL PALSY.

G. G., age twenty-five, came to the clinic complaining of irritability, a sense of exhaustion, particularly after slight exertion, gaseous eructations and poor sleep. Some time ago she developed incipient tuberculosis and entered a sanitarium where she remained for eight months, and recently she has worried over her husband's condition, who has been unable to work on account of postero-lateral sclerosis. During the past two months and occurring several times a week, she would awaken from her sleep, feel dizzy and find that she was unable to move her arms or legs, which felt numb and paralyzed. During the period of palsy she is only half-awake, the eyes are closed, and she is unable to scream. As the drowsy condition wears off, the eyes can be fully opened and the limbs can be moved. Physical examination is negative. This patient has only recently come under observation and it is yet too early to judge of the outcome. During the short time she has been under treatment, however, the attacks of nocturnal palsy have entirely ceased. The treatment has been waking suggestion, applied in the same manner as in the other cases.

An analysis of the above cases will show some points of interest and importance. While the condition of nocturnal palsy occurs occasionally and as a transitory symptom in normal individuals, yet when the attacks are protracted and frequently repeated, it can safely be interpreted as a pathological phenomenon. In the first place it will be noted that the condition of generalized motor paralysis occurs only in the hypnagogic state, and as this wears off and progresses to complete awakening there is a parallel disappearance of the palsy. Consciousness in this hypnagogic condition is either a little hazy or is completely retained, as witness the case of the patient who was able to judge of the length of time she was unable to move by gazing at the watch which hung over her bed. (Case II.) Since the same general palsy has been observed in subjects who are gradually or suddenly awakened from a deep hypnosis, as was pointed out in my first paper, we may safely assume that hypnagogic state is a genuine hypnotic condition, but spontaneously instead of experimentally induced. In fact, in Case II, the gazing at the watch, parallel with the inability to move, reminds one strongly of a state

[5] Carl D. Camp: Morbid Sleepiness, with a report of a case of Narcolepsy. Jour. Abnor. Psychol., vol. ii, no. 1, April–May, 1907.

of hypnotic ecstasy, though no relation seems to exist between hypnosis and normal sleep, in spite of Bechterew's statement[6] that hypnosis is nothing but a modification of normal sleep. Yet it appears from a study of our cases that the spontaneous, semi-drowsy hypnagogic state is practically identical with the experimental hypnotic state. In both there is increased suggestibility, a tendency to paralysis, cataleptiform conditions may appear, and if the state is prolonged, as in the semi-drowsiness of patients suffering from protracted insomnia, hallucinations of sight may arise.

Sudden awakening from a sound sleep seems to bear no relation to the origin of the disorder. In some personal observations on sleeping animals that were suddenly awakened by a loud noise, no temporary muscular rigidity took place, for the animal would frequently jump up and regain its feet at once. If the animal were only half awakened by the stimulus, in a few seconds it would again pass into a natural sleep without any intervening palsy.

This nocturnal palsy, therefore, on clinical evidence at least, seems to possess the following characteristics:

1. It appears only in the hypnagogic state and runs parallel with it.

2. When it occurs in normal individuals it is a transitory and rare phenomenon.

3. Sometimes it follows a strong emotional shock and assumes the characteristics of a recurrent mental state, as in the case published in my first paper.

4. The symptom-complex may occur in hysteria, neurasthenia or psychasthenia. In neurasthenia it appears to be merely symptomatic of the underlying neurosis with its concomitant sense of exhaustion. In hysteria and psychasthenia it is an equivalent disorder in the sense of replacing the narcoleptic attacks in the former disease or the peculiar crises of anxiety in the latter.

5. This nocturnal palsy has a varying duration, from a few seconds in normal individuals, to several minutes or even a quarter of an hour, in pathological cases.

6. The entire symptom-complex is a mental dissociation reacting most strongly on the motor mechanism, and as a purely functional disorder, it is distinctly amenable to psychotherapeutic treatment.

EXOPHTHALMIC GOITER.*

BY EDWARD SWASEY, M.D., WORCESTER, MASS.,
Oculist and Aurist to the City Hospital.

THIS is an old, and yet a new, disease. It is old inasmuch as its written medical history dates as far back as the year 1825, when Dr. Caleb H. Parry, an English physician, first described its symptoms, and he saw his first patient in 1786, more than one hundred and twenty years ago. Although his description was not nearly so complete and full as were those later given by Dr. Graves in 1835, and by Dr. Basedow in 1840, still Osler calls it Parry's disease, in preference to naming after either Graves or Basedow. Graves was a practitioner in Dublin, and the English call it Graves' disease, and because Basedow was a German the Germans call it Basedow's disease. But at the present time, if one looks up the current literature of the subject, he finds it most often referred to as exophthalmic goiter.

And still beyond the year 1825, when it first took its place in our medical literature, who can tell how far back its real history may run, and how its complex symptomatology perplexed and worried previous generations of medical men?

It has, in a way, become a new disease in the increased interest which it has excited since the advent of the various prepared powders and serums, in the past few years, which are giving more promise of control and cure of the affection than have all the previous forms of medication. Moreover, the surgeons are showing more knowledge and courage, together with more skill and caution in operating on the thyroid gland, than was the case ten or fifteen years ago.

Hence it is a subject of great interest to the men in general practice, for they are usually first consulted by the patient. It is of interest to the surgeon because more cures than ever before are being effected by operations, and some of our most skillful surgeons show a larger per cent of cures by the knife than has ever been possible by any other form of treatment. It is of interest to the neurologist because of the serious and complicated involvement of the nervous system, and of interest to the ophthalmologist because of the almost invariable eye complications.

Hence it is a timely and important subject for us all to consider and discuss.

Though exophthalmic goiter has been seen in childhood, and as young as two years of age, and has been known to first appear in persons beyond middle life, it is confined almost wholly to young adult life, and also to females from twenty to thirty years of age. The proportion of females to males is about five to one. We do not know any reason for this great preponderance of females over males, but it is believed that the uterine functions in some way render the vasomotor nerve centers less stable and more easily influenced by shock, fright, grief and worry than in the males. In many cases the exciting cause seems quite definitely traced to some great mental excitement like those given above. In others we cannot find any definite time or experience to trace it to. One author says young adult females with delicate constitutions, clear complexion, blue eyes, blond or reddish hair, and an irritable nervous temperament are especially liable to come to this form of nervous breakdown. More than this we are unable at present to give as a constitutional, predisposing cause. But we do know that the first blow falls on the vasomotor nerve centers. This in turn disturbs the vascular supply of certain organs and among others the thyroid gland. This gland has very definite and

[6] W. V. Bechterew. What is Hypnosis? Jour. Abnor. Psychol., vol., i. no. 1, 1906.

* Read before the Worcester District Medical Society, in Worcester, Oct. 9, 1907.

important functions to perform to keep us in perfect health.

Very recently a French writer has this to say on the function of this gland: "The thyroid gland presides over growth. It supports the physical heat in us at a point which is most convenient for our condition of existence. It regulates the assimilation and destruction of nutritive materials. It is indispensable to the muscular and cerebral functions, and is intimately connected with all transmission of nervous impulses. It is charged with the support of our protective membranes, epidermis and mucous and glandular epithelium. Furthermore, the first symptoms of thyroid insufficiency are of the trophic order, and they are characterized, in short, by an abnormal fragility, a too rapid desquamation of cellular tissues, which isolate us from our external environment." The function of the thyroid and its secretion must be within definite and certain limits, and not too much nor too little.

If too scant or absent we have all the degrees of myxedema in which we have the thick, heavy, dry skin, the feeble and slow pulse, heavy movements both of body and mind and an almost half vegetative existence. If this secretion is increased and absorbed by the lymphatics, for, you remember, the thyroid is one of those curious ductless glands, and is passed on into the blood, we have that group of symptoms which make up the clinical picture of exophthalmic goiter.

And what are these symptoms?

They are a constantly rapid action of the heart, an enlarged thyroid gland and exophthalmos. But these differ in seriousness and in prominence and in constancy of occurrence in different cases. In most cases the first of these to appear is the increase in the action of the heart, and later on the distress of palpitation. With this is a feeling of exhaustion and muscular fatigue and shortness of breath on even slight exertion. The patient may find herself taking long sighing respirations, even when not exerting herself. I have seen one case in which this was the first symptom noticed. At night she sleeps poorly, and dreams many and bad dreams, and awakes in the morning tired and exhausted. Headache is often a troublesome complaint. She is restless by day, and by night tosses about in bed. She can bear but few bed coverings at night and must have a cold room to sleep in, or have a feeling of being smothered. She will wear but light clothing by day, if she be up and about, because she has a feeling of great bodily heat, and she may actually have a degree or two of fever. Sweating is a prominent symptom in many cases, and in some a hacking cough is quite constant, caused by a feeble heart and a passive pulmonary congestion, very likely.

In a severe case rapid emaciation is a marked symptom, and with this an excited nervous state of mind, and her friends may have noticed that she is more easily vexed, excited and worried than has been her habit.

The stomach may be behaving badly and vomiting be troublesome, or only occasional. Tremor of the hands is an early symptom, and the patient may have noticed that she easily drops whatever she may be holding. The knees sometimes give way under her and she drops to the floor. And these, very likely, some or all of them, are all your patient confesses to you when first you see her. These, you see, are not very definite symptoms, and may not point to any well defined disease, and they are common to several.

If you take the pulse, while the patient is quiet and unexcited, it will be probably above 100 or 120 or more, and is a compressible pulse, showing a weak but rapid heart. If you listen to the heart you will find it rapidly and forcibly striking against the rather thin chest walls, for it is probably dilated and covers a large area. You may detect a blowing murmur both from this dilatation and the anemic condition of the blood, and this murmur may be transmitted up along the vessels of the neck. Your patient does not yet show the peculiar eye symptoms, neither is there a noticeable increase in the size of the neck, and the patient herself, nor her family, are aware of any enlargement here.

Of this incipient stage Dr. E. G. Janeway, of New York, has this to say:

"When well developed and presenting all the marked features characteristic of it, exophthalmic goiter could be at once recognized by any tyro, but the case is very different in the incipiency of the disease, or when some of the characteristics are obscure, and we may then give a wrong diagnosis and prognosis." The most frequent mistake he has seen is to regard these as cases of neurasthenia, malaria, lithemia and beginning phthisis. The nervous debility and fatigue and restlessness suggest neurasthenia. The sense of heat, and the sweating and headaches suggest malaria. The disturbance of the stomach and bowels, the fatigue, the action of the heart and other symptoms, suggest lithemia; and, lastly, the whole array of these symptoms, including the emaciation, the sweating, some temperature, and if there be a cough also, he has seen mistaken for commencing pulmonary tuberculosis, and he has seen patients with advanced exophthalmic goiter who were thought to have died from pulmonary tuberculosis when autopsy showed none existed.

These symptoms which we have considered may be present for some weeks or months before the enlargement of the thyroid gland is noticed by the patient or her family. Usually, however, if careful search is made the physician will discover some enlargement, and most frequently in the right lobe of the gland. It can be made more evident by having the head thrown well back. Then, usually, the last of these symptoms, following the rapid pulse, the enlarged thyroid, comes the exophthalmos. In Riedel's Clinic in Jena these several symptoms were found in this proportion: goiter, 100%; rapid heart action, 94%; palpitation, 94%; exophthalmos, 92%; mental disturbances, 68%; tremor, 66%; headache, 42%; sleeplessness, 40%; sweats, 36%; emaciation, 30%; von Graefe's sign, 30%; vomit-

ing and diarrhea, 28%; Stellwag's sign, 22%. In another German clinic the enlargement of the thyroid was absent in but 3 out of 58 cases.

Cases differ very markedly in their progress from the onset. Some have a mild course and the patients have never been seriously ill, and very likely keep about their work and daily life in comparative comfort. I saw such a case in my office not many weeks ago. She was past fifty years of age, and regarded herself in very good health. But she had the protruding eyes, with a line of sclerotic showing below the upper lids; she had the rapid heart, more than 100 to the minute, and she had the enlarged thyroid to a mild degree. She confessed to some palpitation on mild exertion. This had been her condition for many years, for she has been under my care for several years and has had this same appearance. It was a well-marked but mild type of Graves' disease. We see on the streets and in the stores young and middle-aged women with the eyes prominent and a white line showing above the iris; you may be able to see that the neck is enlarged, perhaps, more on the sides. If you could examine the pulse and heart in these cases, very likely you would find it rapid and rather weak. I saw in the electric car in Boston, not many weeks ago, a young lady with the characteristic eye symptoms, she was nervous and fidgety, and had a florid complexion. I had no doubt she would show the other objective, and confess to the subjective, signs of this affection, if carefully examined.

But, on the other hand, I have followed a case where the symptoms, from the first, indicated a very grave type, where the goiter was large, throbbing and vascular, the emaciation was rapid, the pulse never below 120, or if so but a very short duration; the headache, at times, was very severe; for a few days only was there a prominence of the eyes and never extreme; sweating was never present but a rather hot, dry skin, and at times, an erythematous blush along the inner sides of the arms. Von Graefe's sign was not seen in any stage of the disease. She subsequently came under the care of one of the leading surgeons of the country, who had seen and operated on a great number of these patients. She was examined by Dr. Kocher, of Berne, Switzerland, one of the authorities of the world in exophthalmic goiter. She was kept in bed for two weeks, carefully preparing, by all the methods of medication, to bring her into a fit condition for partial removal of the thyroid. But any form of medication was only palliative, and did not in any way reduce the size of the goiter, or materially reduce the rapid action of the heart. At the end of two weeks there was partial removal of the thyroid. She survived the operation but a few days, as all the symptoms were more extreme immediately following the operation. These surgeons of very large experience regard it as a very grave, if not malignant, form of exophthalmic goiter. But even in this case the exophthalmos was only of passing duration.

In contrast to this, let me refer to another case that I saw some years ago. The young lady had been going about our streets for a year or two in comparative good health. There was very decided exophthalmos all this time, but it became so extreme in the left eye that the lids could not be closed over the cornea. This exposure brought on inflammation and ulceration of the cornea and on to panophthalmitis and enucleation. This destructive process was well established when I first saw the case, and I could not then draw the upper lid down over the globe. This patient had a rapid and feeble heart and had had this condition from the time of some severe mental shock some years previous. There was a well marked goiter, but not very large, and more on the right side. The etherization and shock of the enucleation had no bad effects on her condition, and the other eye was markedly improved in appearance. Thus, in a very limited experience, one may see how these cases differ in seriousness and how varied are the symptoms. We may have all the clinical features present but in a mild and chronic form. We may have a very severe type of the affection and have practically no exophthalmos. We may have extreme exophthalmos, and all the other symptoms not at all severe.

Next in point of frequency in its appearance, after the rapid action of the heart, comes the enlargement of the thyroid gland. And this symptom was absent, as we have seen, in but 3 out of 58 cases. Or, taking Riedel's clinic, it was present in every case.

In simple goiter we have, of course, an enlarged thyroid gland, and this enlargement is due chiefly to the dilatation of the alveoli with colloid material and increase of connective tissue; a local tumor, but without definite constitutional symptoms. In exophthalmic goiter, on the contrary, the colloid material is lesser in amount, while the glandular element is increased in number and size and the epithelial lining of these alveoli is increased. Given this condition, with a greatly increased blood supply, and we soon have coming into the blood in great excess that peculiar thyroid secretion, the active principle of which is a globulin containing iodin, called thyroglobulin. It has gone beyond healthy and normal limits and has become a toxin. And just this is the modern interpretation and explanation of the symptoms of exophthalmic goiter. It is a toxemia, and the factory that is supplying this toxin, working night and day under high pressure, is the thyroid gland. What was designed to be our conservator, our health giver, has now become our executioner and is driving its victim to death.

If in the way of illustration, we let the heart and its nerve supply be compared to a stage-coach drawn by six or eight mettlesome and fiery horses, and on each horse is seated a postilion; from the bits and bridles on these horses go the reins up to the hands of the driver on the box of the coach. The mettlesome horses shall be represented by the muscles of the heart; the postilions by the intracardiac nerve ganglia; the reins by the pneumogastric nerves which go up to the driver's seat, in the floor of the fourth ventri-

cle. This whole outfit may and does behave beautifully and goes along peaceably in perfect health. It may go to wreck and ruin for two reasons. Let those little imps, the postilions, became stimulated and reckless by too much fire water, and ply their horses with whip and spur; or, by some mishap, let the driver on his seat lose control of the reins, and you know very well what will happen to that coach and its horses. There will be a runaway, which may not be checked until exhausted in death, or it may be again taken under control and rescued from a total wreck. This thyroglobulin is the fire water that these postilions are imbibing and it sets them on fire. They use their spurs and whips on the horses on which they are seated, the cardiac muscles. They are also receiving aid and encouragement from an outside source, the lower cervical and first dorsal sympathetic nerve ganglia in the neck, for they belong to the same family as do the cardiac ganglia, and will behave the same way under the stimulus of this fire water. Some of the older writers believed the seat of this trouble was in the floor of the fourth ventricle; that there was partial paresis of the nerve centers here; that the driver on the box, to continue our illustration, was lax in the control of the reins, and that the little fellows on the horses were taking advantage and control of the situation to put their horses into a stampede.

It was not till 1886 that Moebius first definitely connected this disease with disorder of the thyroid gland. He, at that time, believed it was a thyroid neurosis. Basedow believed it was a peculiar blood condition, a chronic state of anemia.

But modern laboratory investigations have gone beyond these mere beliefs, in a neurosis and blood dyscrasia, and have shown that this thyroglobulin is the toxin that is playing the mischief with these sympathetic nerve ganglia.

In a recent article Dr. MacCallum, pathologist at Johns Hopkins, gives a list of 58 patients with exophthalmic goiter. In 41 of these the symptoms were what he calls "typical," and in every one of these the changes in the character of the thyroid gland were also "typical." The veins were large and distended with blood, and were easily torn, the epithelial lining of the alveoli was increased; the colloid material usually, though not always, diseased.

He says: "From what has been said it is seen that with the appearance of definite symptoms of exophthalmic goiter there is always the same change in the thyroid." In the 17 remaining cases the symptoms were "indefinite," and in these the changes in the character of the thyroid were "indefinite" also.

After post-mortem examination of the cervical sympathetic ganglia, the parathyroids, the nerve centers in the medulla, he comes to this conclusion: "On the whole, therefore, the only lesions in this disease, which are palpable and constant, are those of the thyroid and of the lymphoid apparatus and of the thymus."

Some German and French investigators believe, also, that the parathyroid bodies have taken on extra activity and are adding their peculiar toxic secretion to the blood. These little satellites of the thyroid gland are usually four in number, two on each side, and are situated behind the gland and around the terminal branches of the inferior thyroid vessels. They are small, ovoid or lenticular bodies, and often resemble small masses of fat in consistency as well as in color. They had escaped notice, or at least their great importance had been overlooked, until the year 1880, when they were accurately described for the first time by Sandstrome. Then they were allowed to be forgotten again for fifteen years, but since 1895 they have received more careful study.

MacCallum examined these parathyroids post-mortem in 16 cases, and he found them practically normal in every case, and from this he says: "On the whole it seems improbable that the parathyroids have anything to do with the symptoms-complex of exophthalmic goiter, when we consider these very slight anatomic lesions with the advanced changes in the thyroid."

The third member of this group of symptoms, the exophthalmos, is of least importance, though it be the most evident, and it is usually last to appear. The eye is pushed forward by the enlarged veins and tissues of the orbit. As we have seen, it may be slight; it may be extreme; it may be transitory; it may be permanent.

In the latter case, and in milder forms of exophthalmic goiter where emaciation is not severe, a fat deposit in the orbit and increased connective tissue may account for its long continuance. Usually the sight of the eye is not impaired. The von Graefe sign which has been referred to, and which at one time was considered of great importance, is the failure of the upper lids to follow the eyeballs in looking down, as they do in health. The Stellwag sign is an apparent enlargement of palpebral opening. The treatment of exophthalmic goiter, both medical and surgical, has taken on renewed interest and careful study in the past few years. It is not within my province, nor is it my purpose, to attempt to go fully into this broad field, even if I had the time at my disposal. I wish only to refer to the general principles underlying both.

Rest in bed, if the case is in any way serious, is, and always has been, an important part of the treatment. The list of drugs that have been used is a long one. But it should be remembered that some cases will recover, or greatly improve, under quiet and rest, with very little medication.

The modern plan of treatment is to introduce into the blood something that will counteract or neutralize this toxic thyroglobulin. As myxedema has been cured by extracts of the thyroid gland, the conclusion was natural that if animals could be rendered myxedematous they would supply us with something that would cure exophthalmic goiter. So dogs, sheep, goats and other animals have had their thyroid glands removed. The milk of these sheep and goats has been used after careful laboratory preparation. It is given in powder form. One of these is a

white powder called Rodegen, and is a German preparation. I have seen it used with great benefit, and while it had no radical curative effect and did not reduce the size of the goiter, it certainly improved some of the more distressing symptoms.

Then there are the different serums prepared from the blood of myxedematous animals. I have never seen them used, but Dr. John Rogers, of New York, has made especial study along these lines. He has reported some good results, and hopes that still more improvement will follow. He has treated 41 cases in this way with 8 cured, 25 improved, 2 died and 6 no result given. In 28 cases, reported by others, there were 3 cured, 16 improved, and 9 unimproved. The conclusions reached by these observers are these: if the goiter is small and soft the chances of improvement or cure are good; if the thyroid is hard and large the case is doubtful. Rogers calls his serum preparation a specific cytotoxin.

The x-ray has been used on these goiters, and much improvement has been seen in reduction of their size and in the general symptoms.

Dr. Chas. Mayo frequently prepares his patients for operation by a course of four or six weeks of its use. He believes it causes destruction of the efferent lymphatics and so shuts up the channels of entrance of these toxins into the blood. Some other observers have this to say of the results of x-ray treatment: It has induced unmistakable benefit in all cases; the goiter was reduced in size and as it subsided the nervous symptoms vanished with it. The patients all increased in weight. In some no relapse in fifteen months. The soft vascular goiters are the most readily influenced, and the prognosis is better the more recent the goiter.

And, finally, What has been the record, and what may we hope for from the surgical treatment of exophthalmic goiter? It will always be a serious operation, but if medical treatment has failed, after a few months of its employment, to bring marked improvement in these patients, they should have the benefit of surgical treatment, seems to be the conclusion of our men of largest experience and observation. Some other conclusions they have arrived at are these: Do not wait too long before resorting to surgery, for these patients are losing strength and power of resistance from a weakened heart from the effects of this toxemia. For this reason, it is believed, by some operators, there is more than ordinary risk in general anesthesia, and some patients have died from its effects even when no operation has been performed. The increased congestion of the head and neck also adds to the hemorrhage, for it is considerable at best, and the coats of the blood vessels are thin and tender and are increased in number. Some advocate the use only of local anesthesia, by eucaine, for this reason, and also that they can more surely avoid injury to the recurrent laryngeal nerve, if the patients are conscious. Mayo uses general anesthesia, and he has a brilliant record of recoveries.

The several operations that have been performed are: the removal of the lower cervical and upper dorsal sympathetic nerve ganglia; the ligature of the thyroid vessels, and partial removal of the gland. They all have some cases placed to their credit and have their advocates. I will consider, and that only briefly, the partial extirpation of the gland.

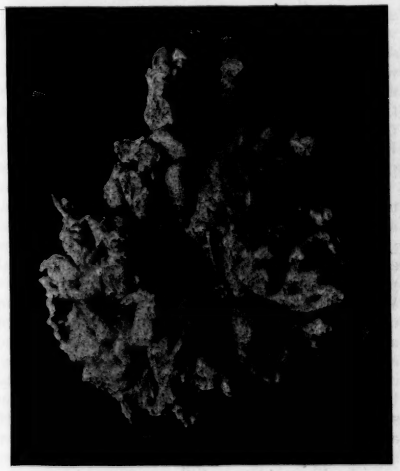
Friedmann says: "Enucleation or resection of part of the gland is the only means known to date by which exophthalmic goiter is permanently cured, and with internal treatment the mortality is 12%, and that permanent cure seems to be out of the question." "All goiters," says Kocher, "when there is a noticeable increase in size, should be removed, and especially when even in slight degree symptoms of exophthalmic goiter are present, as operation is the best means of preventing further development of this serious disease." He advocates the removal of three fourths of the gland. Halsted, of Johns Hopkins, advocates this operation, but he is very careful and solicitous about not only removal, but of injury in any degree, or even disturbance of the circulation of these parathyroids, for he, with others, has learned that injury to these is the cause of post-operative tetany, a very serious condition. He is careful to leave a liberal portion of the gland that surrounds the inferior thyroid vessels and these adjacent bodies. Complete removal of these little bodies, experimenters have found, in the lower animals, is followed by an acute fatal tetany, which supervenes in a few hours or a few days.

In all the operations on the thyroid, the gland should be handled as little as possible and then with the utmost gentleness, as any rough handling or squeezing forces this toxic secretion out of the gland into the circulation, and just this extra amount may turn the tide and hope of recovery against the patient. Those who have seen Dr. Charles Mayo operate on these patients say he is very delicate and gentle in handling the gland, and they attribute no small degree of his success to this caution. In estimating the relative success and cures from thyroidectomy it should be remembered that the surgeon is usually called upon to operate after medication has failed and an operation is the last resort; that the goiter may be large and vascular, and from such the hemorrhage would be serious; and that the heart and vital forces are possibly weakened by too long delay. One authority says that these only are the patients who are liable to die from the operation. It would seem that the future of this operation is most encouraging when we are told by Friedmann that the report from four large German clinics shows 109 patients operated on, and only 8 deaths, with 75 permanent cures, 23 much improved and 3 unaccounted for. He, himself, gives one record of 20 operations with 15 cured and 5 much improved. In another report I find there were 50 patients operated upon with 36 cured, 6 much improved, 1 no improvement and 7 succumbed to heart failure in twenty-four hours.

The use of eucaine locally has brought the

mortality down from 12% to 8%. Mayo in one list of 42 operations had only 1 death.

Including those given above and others I find on record we have a total of 360 operations on the thyroid gland for exophthalmic goiter, and only 28 deaths, or 13 recoveries to 1 death.



Clinical Department.

A CASE OF NON-ULCERATIVE FOLLICULAR ILEOCOLITIS.

BY FRANK E. STETSON, M.D., AND OSCAR S. CREELEY, M.D., NEW BEDFORD, MASS.

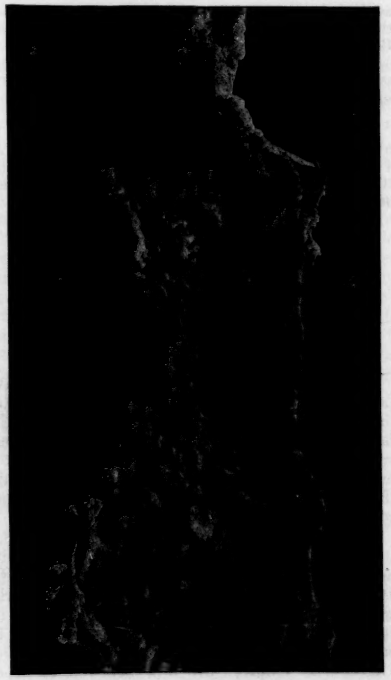
Serero Lynch, born in the United States, aged eight months, was admitted to St. Luke's Hospital, Aug. 17, 1907. Diagnosis: Ileocolitis follicularis non-ulcerativa (primary), intestinal absorption (secondary). Result. Died Aug. 18, 1907.

Urine color. — Normal to slightly cloudy. Reaction acid. Specific gravity (?) Albumin, small trace. Sugar, 0. Sediment, few pus and red blood cells, many fatty casts, few small broken-down round cells with fat drops within the cell.

Blood. — White count (one half hour after death), 53,000. Differential count: Lymphocytes, 75%. Polymorphonuclear, 25%.

Father and mother living and well. Never sick before.

Thursday, Aug. 15, 1907, baby quite fretful and pale. Bowels were slightly loose at this time. Character of the stools not noted.



Friday, baby about the same and played as usual. Was taking his food all right at this time.

Saturday morning, Aug. 17, 1907, between 3 and 4 o'clock, baby vomited his milk after having had bottle. Vomited again at 4.30 A.M. Then went to sleep. On way to hospital appeared to feel better. Admitted at 6 A.M., Saturday, Aug. 17, 1907.

Physical examination, Saturday, 9 A.M., Aug. 17, 1907. — Robust-looking child of eight months, slightly pale. Did not look or act very sick, but was put to bed. Eyes, pupils equal. Neck, no retractions or glandular enlargement. Tongue, clear. Lungs, normal. Heart, sounds clear, no murmurs, regular, rate 126. Abdomen, slight distention but no rigidity or tenderness over any area; very slight rosary was made out but no other evidence of rickets. No eruptions or scars seen on child's body. Extremities, normal. Temperature, respiration and pulse (see chart).

AUTOPSY FINDINGS.

Incision was made in the usual manner from sternal notch to pubes. The intestines were markedly distended with gas but empty. The bladder was opened but showed nothing abnormal. Stomach and intestines next removed. Stomach appeared perfectly normal except for several little eroded places; these were mostly split pea in size and were colorless, and had no redness about the periphery; seven or eight of these were seen.

The intestines appeared normal except that in the last two feet of the ilium, non-ulcerating follicles were noted. These were grayish white in color and varied in size from pin head to split pea in size. These lesions were most abundant just before the ileo-cecal valve was reached. The mesenteric lymph glands were markedly enlarged. Some of the glands were as large as a large pea. The kidneys were removed and saved for further examination. Unfortunately, the specimen was destroyed. The kidney macroscopically was markedly injected throughout the pelvis.

The lungs were perfectly normal. The thymus gland, which in this case covered practically the

anterior aspect of the heart, was removed and appeared normal. The heart was opened and showed nothing abnormal. All four chambers were carefully examined. The spleen and liver, together wth the gall bladder, appeared perfectly normal.

The child did not appear ill on admission and played with its toys more or less throughout the day. It had 2 dr. of castor oil which caused it to have several loose movements. These movements were not, as far as I know, characteristic of any conditions. They were greenish in character, but showed no evidences of curds, blood or mucus, and were in no sense characteristic.

The child had an apparently comfortable night Saturday and took its barley water well. Sunday morning at 9.30 while going through the ward I noticed that the child was breathing with a good deal of difficulty, and watching it for a few minutes saw that the breathing was of a Cheyne-Stokes character. This persisted to the end. As the abdomen was not tender or rigid and as the baby appeared very sick at this time I examined the ears thinking perhaps it might have a middle ear. Both drums appeared perfectly normal.

Treatment. — Castor oil, 2 dr. Brandy, 10 drops every hour for four doses. Bowel irrigated with warm saline solution.

Diet. — Barley water.

Temperature. — On admission, 104.4°. At 12 o'clock noon, 101°. At 4 o'clock P.M., 100°. At 4 A.M., next morning, 103°. At one hour before death, 105°. Pulse at these corresponding times varied between 104 and 72.

Medical Progress.

PROGRESS IN GYNECOLOGY.

BY W. L. BURRAGE, M.D.

GONOCOCCUS INFECTION.

L. EMMET HOLT and other recent writers have pointed out that gonococcus infection is a better name than gonorrhea, time honored though the latter be, because it does not carry with it necessarily the stigma of a venereal disease. This is especially important in vulvo-vaginitis in children where there is no suspicion of a direct venereal origin of the infection.

Prevalence. — The prevalence of gonococcus infection in women varies within wide limits according to the views of different gynecologists. It is by no means uncommon in little girls, especially in institutions. This subject will be taken up in some detail further on. Suffice it to say here that most of the cases of purulent vulvo-vaginitis in children are now believed to be of gonococcus origin. Lomer found the diplococcus in 60% of the gynecological patients of Schroeder's clinic. Saenger and Schwartz [1] put the percentage of gonorrhea among all their patients, hospital and private, as low as twelve. Taylor, viewing the matter from the standpoint of the venereal specialist, says that 12% is a conservative estimate of the gonorrheal origin of all uterine diseases.

This great diversity of opinion can be accounted for in several ways. First, the difficulty of finding the scattered gonococci in the chronic cases. In the acute cases and under favorable circumstances, the gonococci are often not very numerous, only four to a dozen being found in one microscopical field. Second, we know that under certain conditions the cocci die, whether from lack of suitable nutrient material, the activity of the phagocytes or other cause. Although dead, the tissues in which this occurs are still infected, perhaps because of the "gonotoxin" generated in the dead cells. Third, the class of patients treated. One would expect to find gonorrhea most common among prostitutes. Statistics prove this to be the case. Among 533 prostitutes, sick and well, examined in the regular routine by Huber [2] 59.6% had gonorrhea. Prowe [3] found gonorrhea in 76.9% of 407 sick prostitutes in San Salvadore, Central America. Zweifel thought the number of women in his private practice who were ill because of the gonococcus was from 10% to 11%. Some writers place the percentage among private patients as high as 20. Obviously, information on this point is difficult to get for few statistics are published, physicians not caring to go on record.

Tissues affected. — The organs in woman usually affected by the gonococcus are, the vulva, urethra, vagina, uterine canal, and Fallopian tubes. Destructive inflammation of the tubes and ovaries with peritonitis is common. Gonococcus inflammation of the rectum and gonococcus infection of the bladder with secondary ascending inflammation of the ureters and kidneys are not rare. Huber [4] found rectal gonorrhea in 24.6% of 318 prostitutes who had gonorrhea.

That the disease is a serious one and rebellious to treatment there can be no doubt. The Committee of Seven of the American Medical Association, in a recent report to the association, asserted that 80% of the deaths from female pelvic disease are due to gonococcus infection. We have to consider not only the manifestations of the disease in the genito-urinary organs but also its effect on distant organs, such as gonococcus arthritis, especially of the knee-joint, and its effect upon the system, anemia and debility. F. R. Sturgis [5] draws a parallel between the constitutional effects of syphilis and gonorrhea. He considers that many of the same organs are attacked by both diseases and that gonorrhea may be likened to syphilis in the seriousness of the systemic disturbances it causes, not the least of these being impoverishment of the blood state and rheumatism with attendant gonococcus endocarditis. Out of an ample experience as clinical professor of venereal diseases in the University of the City of New York he deprecates the silly belief of those who consider gonorrhea as no more important than a cold in the head.

Characteristics of the gonococcus. — The gonococcus has an especial affinity for the mucous membranes of man. It is not, as formerly thought, limited in its place of growth to the columnar epithelium. It has been found in the

sub-mucous tissues of the vagina by Mandl; in squamous epithelium by Bumm, Touton and others; in the thrombosed blood vessels of the bladder, in the serosa of the peritoneum, and in the substance of the ovary by E. Wertheim; in the connective tissue of the Fallopian tubes by Kraus; in the rectal mucous membrane by Fritsch; in the uterine muscle by Madlener and Menge; in the decidua and placenta of a nine-months pregnancy by Maslovski, and in the urine of cystitis by Melchoir. Kroenig [6] found gonococci in the lochia of over 10% of 296 lying-in women who had had childbed fever.

Lobenstine and Harrar [7] found that the average birth-weight of the babies of gonorrheal mothers is less than that of babies of normal mothers. Their deductions were based on the observation of 50 babies of gonorrheal mothers without fever, 50 babies of gonorrheal mothers with high temperature and 150 of normal mothers. Not only is the average weight less but there is a greater permanent loss, those of gonorrheal parentage gaining at the end of ten days only 10.9%, while babies of normal mothers gain 49.3%. They consider that gonorrhea occurring in the mother in the later months of pregnancy is the cause of a large number of premature births.

In places other than the genital organs and their neighborhood it has been found in the pus of inflamed joints by Stern and Jacquet, in the pus of an inflamed tendon sheath by Kroenig and in the mucous membranes of the oral cavity, nose, middle ear, and the conjunctiva of the new born by Dóhrn, Rosinski, Leyden, Kroenig and others. The gonococcus has been isolated from a thrombus of the pulmonary valve in a case of ulcerative endocarditis by Lenhartz, and in the blood current by Amann, Unger, Von Leyden and Michaelis. Amann proved the identity of the gonococcus by stain and culture, and, by experimental inoculation of the human urethra, produced a typical attack of gonorrhea complicated by inflammation of tendon sheaths.

The gonococcus may be cultivated outside the body by using as a culture medium human serum in the form of hydrocele, ovarian or ascitic fluid together with agar, and may be kept alive for several generations. It is to be noted that it grows only in neutral or alkaline media. Therefore the normal vaginal secretion made acid by the lactic acid bacterium of Doederlein is hostile to its growth.

Gonotoxin. — De Christmas [8] found that there is a toxic product of the gonococcus developed after the cultured organism is dead, and that this is capable of producing suppuration when injected into the eye of a rabbit. His work was confirmatory of the investigations of Wassermann [9] and Maslovski [10] who experimented with pure cultures of the gonococcus in nutrient media to which, after the cocci had attained their full growth, alcohol was added to destroy them and to precipitate the albumin. The dead cocci with the albumin were then filtered out of the fluid, mixed with sterile water, the alcohol driven off by heat, and the fluid so obtained used to inoculate rabbits and guinea pigs. The injections were found to be exceedingly poisonous and produced both local inflammations and pyrexia typical of gonorrhea. The filtrate when injected into the animals had no effect, showing that the poisonous properties were in the dead cocci. Maslovski considered that when the gonococci die a gonotoxin is developed in the body of the cocci, an endotoxin. It is to this toxin that the symptoms of gonorrhea are due rather than to the development of the gonococci in the organism. He found the toxin to have both a local action, inflammatory and suppurative, and a general action, elevation of temperature, loss of weight, etc. Repeated injections of the gonotoxin produced no immunity, neither did injections of the pure cultures; therefore there is no immunity in gonorrhea, and reinfection may take place in the same individual an indefinite number of times. This coincides with the clinical observations of the disease in man. According to the most recent and approved views mixed infection is not often present in gonorrhea. In other words the gonococcus generally has the field to himself. By the destruction of the surface epithelium as a result of gonococcus inflammation the conditions are made favorable for the invasion into the tissues of the staphylococcus, streptococcus and colon bacillus, which are found frequently after the gonococcus inflammation may be said to be at an end. It is likely that some, at least, of the manifestations of the later stages of gonococcus infection are due to the formation of the gonotoxin and not to the invasion of other organisms. Taking advantage of the discovery of the gonotoxin some attempts have been made to treat gonococcus infection by the injection of antigonococcus serum [11] but so far the results are not convincing.

Curability of gonococcus infection. — Julien [12] discusses the curability of gonorrhea, adopting Wertheim's view that in chronic gonorrhea a fresh attack may be lighted up by a new culture ground; there is no real immunity. That is to say, if a man having chronic gleet marries a healthy woman she acquires gonorrhea from him and then her gonococci are able to set up an acute process in the husband's urethra. This is the opinion commonly held to-day, and is founded more on clinical observation than on bacteriological evidence. The importance of a man being cured entirely of gonorrhea before he is married is made doubly apparent. Most authorities maintain that the disease may be eradicated by persistent treatment conducted over a long period of time. Every individual who has once had gonorrhea should be assumed to be infected still until the contrary has been proved.

Clinical course and symptoms. — Acute gonorrhea as seen in prostitutes is characterized by a chill, rapid pulse, elevation of temperature, pelvic

pains, burning and smarting on urination, and, in the course of a few hours, by a leucorrhea, at first mucous, soon becoming purulent, the pus often being of a greenish hue and mixed with blood. The symptoms begin from twenty-four hours to eight days after infection. Exceptionally they may begin before twenty-four hours or may be delayed as long as fourteen days. The disease begins most frequently in the urethra, just as in the male. The meatus urinarius is protected in the young woman, as pointed out by H. A. Kelly,[13] by the labia urethræ. In the beginning of coitus the glans penis pushes against the labia and separates or invaginates them, bringing discharge from the male meatus directly in contact with the mucous membrane of the female meatus. The glands of Skene lie just in the edge of the female urethra; they are lined with columnar epithelium, the favorite habitat of the gonococcus. Therefore it happens that these glands are frequently infected. Another favorite seat of infection is the glands of Bartholin on either side of the entrance of the vagina just outside the hymen. These also are lined with a layer of columnar epithelial cells. The impact of the penis in its endeavor to enter the vagina causes more or less trauma of the tissues over these glands and gonococci-laden discharge from the male meatus is rubbed into them. The vagina, lined with pavement epithelium and bathed in an acid secretion, is infected, although less commonly than the urethra. The younger the patient the more apt is the vaginal mucosa to be infected, because in the young the pavement epithelium is softer and more like columnar epithelium, hence the frequency of gonococcus vulvo-vaginitis in children.

The mucous membrane lining the cavity of the cervix uteri is thrown into folds and has branching glands lined with ciliated columnar epithelium. This is the situation next most commonly affected. Here the disease is prone to lurk just as in the glands of Skene and Bartholin. An acute gonococcus infection generally involves the urethra, vagina and cervical canal. It runs a course of six weeks. The inguinal lymphatic glands which receive infective material from the vulva and lower vagina may become inflamed and may suppurate, and the patient has a "bubo." This complication is more common in women of uncleanly habits. A gonococcus arthritis occurring during the course of the disease is a frequent complication.

Acute gonorrhea as described, except among prostitutes, is relatively rare. The symptoms of the invasion of the gonococcus in the genital organs of women are generally not pronounced. They are often a smarting on urination and an increase of vaginal discharge. The only history of infection may be that a mucoid, unirritating leucorrheal discharge became purulent and irritating. Even this may be absent. Perhaps the first symptoms to lead a patient to consult a physician will be due to tubal disease, a cervical catarrh or a vulvo-vaginal abscess, so insidious are the stages of invasion of this disease. In the chronic forms of gonococcus infection the leucorrhea loses its purulent character and is generally abundant. The symptoms depend on the organs chiefly involved, whether vulvo-vaginal glands, urethra and Skene's glands, uterine canal or Fallopian tubes and peritoneum.

Vulvo-vaginitis in little girls. — Fluor albus in children was first mentioned in the eighteenth century, and although it has been referred to in treatises on the diseases of women and children its serious import has not received sufficient attention. Sara Welt-Kakels[14] observed in her clinic at the Mount Sinai Hospital, New York, during the ten years from 1893 to 1903, 190 cases of vulvo-vaginitis, or 1.6% of all the children treated. The largest number occurred in children between the ages of two and five years and the disease was rare after the tenth year. Not all of the cases were of gonococcus origin. L. Emmet Holt[15] reports the results of investigations made in the Babies Hospital and other institutions for children in New York. When the new building of the Babies Hospital was opened in 1902 a child with gonococcus vaginitis was admitted inadvertently. From this child, in spite of new wards and the cleanest of surroundings, 11 fresh cases developed, including 3 of gonococcus arthritis. The rule was thereupon established to admit no female child without a microscopical examination of the vaginal secretion. In another infants' hospital in the same city where there was said to be no vulvo-vaginitis, smears were made from the vaginal secretion of 100 infants and young children, the cases being taken in order without selection. Twelve showed a yellow purulent discharge, and pus and gonococci were found in all by microscopical examination. This must be considered a large percentage, as most authors place the frequency of vulvo-vaginitis as about 1%. Not all cases of vulvo-vaginitis are of gonococcus origin, the cause of the so-called catarrhal cases being unknown. The gonococcus form comprises nearly all those in which the discharge is purulent; it is the most severe and most rebellious to treatment besides being the most common. Although the inflammatory symptoms disappear at the end of four to six weeks, exacerbations occur. One author reports finding gonococci in the discharges after the disease had lasted four years. Gonococcus vulvo-vaginitis is contracted sometimes through sleeping with the mother, sister or other female relative; as a rule the infection is indirect and accidental, being transmitted on contaminated bed linen, towels, sponges or even by bathing in the same bath tub. A marked instance of the last mode of contagion was an epidemic of vulvo-vaginitis which occurred in the city of Posen, Germany, in 1890[16] in which 236 school girls, aged from six to fourteen years, were taken ill inside of eight to fourteen days with vulvo-vaginitis. They had all used the same public bath house, where, on account of limited accommodations,

[16] Referred to by Welt-Kakels, *loc. cit.*

two or more children were required to bathe in one tub.

There are grounds for the belief that adhesions of the labia and prepuce, occlusion of the hymen and hematocolpus, deformed uteri, and diseased Fallopian tubes are the sequelæ of this disease. The complications are acute purulent peritonitis, arthritis and ophthalmia. Latent gonorrhea has been referred to. It explains why the gonococcus, even after years of apparent cure, may regain its full virulence. This brings up the question of the advisability of marriage in persons who have had gonorrhea.

Gonorrhea and marriage. — In the case of the male it is the custom for genito-urinary specialists to advise that marriage is permissible when there are no shreds in the urine, when the gleety discharge from the urethra has ceased, and when repeated examinations made several days apart show no gonococci in smears made from mucous from the meatus. There are cases on record where these precautions have been observed and yet a gonorrheal process has been set up in the previously healthy wife. Other instances are numerous where no disease was noted in the wife until the husband became reinfected by intercourse with a prostitute. It would seem as if reinfection was at the root of the trouble, and would explain many of the otherwise inexplicable cases of gonococcus infection. In the case of woman repeated examinations of mucous from the meatus urethræ, after expression of the urethra; of mucus from Bartholin's glands, and mucus from the canal of the cervix uteri; found to be free from gonococci, prove that the disease is cured. It is to be remembered that clinical evidence shows that the disease is more easily transmissible by a previously infected woman at or about the time of menstruation. This fact is explained by the congestion of the genital organs always present at this time with the consequent liberation from the tissues of more abundant flora of gonococci. Something may be due to a diminished acidity of the vaginal secretion at this time, ordinarily destructive to the gonococcus. Therefore, examinations for the gonococcus should be made, if possible, near a menstrual period.

Instances will occur to the mind of every practitioner of large experience where a man who has had gonorrhea has had subsequently a family of healthy children. This must be considered the exception, the rule being that such a man's wife is sterile or has only one child, and she suffers in the future from uterine disease. Prostitutes are notoriously sterile. The sterility is supposed to be due to gonococcus endometritis, to destruction of the ciliated columnar epithelium of the Fallopian tubes by gonococcus inflammation, or to closure of their caliber from the same cause. Be this as it may, there can be no doubt, on clinical grounds, that gonococcus infection is one of the most frequent causes of sterility in women.

Diagnosis. — In the acute form of gonococcus infection the diagnosis is not difficult. It is established by a history of a suspicious intercourse followed in a day to a week by the classical symptoms and the finding of the gonococcus in the pus of the discharges. In the subacute and chronic forms the diagnosis is hard to make. It rests on a history of an unclean coitus; on the history of frequent and painful micturition (an acute urethritis being strong presumptive evidence of gonorrhea). It is not an uncommon experience to have the patient tell her physician that a little while after marriage she noticed that she had a leucorrhea which stained her linen and that her water smarted when she passed it. Questioning the husband at some subsequent time it is learned that he has had gonorrhea. Great tact should be exercised by the physician not to push his inquiries with the wife too far because of the danger of causing marital troubles that no doctor can cure. In gonococcus infection of the innocent, by far the most common variety of the disease, it is seldom advisable to inform the woman of the exact nature of the disease she has acquired. As a rule too great frankness on the part of the physician is to be deprecated. More is to be expected from missionary work with men who should appreciate the dangers they run and the risks to which they are subjecting those nearest and dearest to them.

Occasionally a patient will describe having had an adenitis in the groin or arthritis. This is rare. The presence of the "maculæ gonorrhoicæ" of Saenger [17] is presumptive evidence of gonorrhea. These consist of a redness and puffiness similar to the wheal caused by a flea-bite at the orifices of Skene's glands and Bartholin's glands. The redness persists long after all active suppuration has ceased.

In examining a woman for chronic gonococcus infection, it is important that she should come to the examination without previous douching or cleansing of the genitals. She is to be examined in the dorsal position. The labia are separated and the discharge removed gently with pledgets of absorbent cotton. Smears are made from the pus expressed from the orifice of a gland of Bartholin. The physician's forefinger inserted into the vagina making backward pressure on the perineum to gain room and to avoid pressure on the urethra. Then the urethra is stroked with the forefinger from above downward and any secretion which may be present is expressed and gathered on a sterile probe or applicator and transferred to a cover glass. The orifices of Skene's glands are carefully scrutinized for the presence of surrounding redness and pus. A speculum is introduced into the vagina and with the aid of a sterile applicator a smear is made from the discharge from the cervical canal.

The detection of the gonococcus in the discharge by staining and Gram decolorizing is proof positive of the disease. Some authors (Calmann, Klein and Fritsch) have insisted on the necessity of making cultures of the gonococcus. On account of the great difficulties surrounding the growing of this bacterium outside the tissues of

[17] Centralbl. für Gyn., 1896, p. 1073.

the human body this is seldom done in practice, although it may furnish valuable confirmatory evidence. Finding the gonococcus in bits of tissue removed at the time of operations on the genitalia is proof of the nature of the diseased condition. Too often the diagnosis of chronic gonococcus infection must be only a probable one because of the difficulty in finding the gonococcus.

REPORT ON MENTAL DISEASE.

BY HENRY R. STEDMAN, M.D., BROOKLINE, MASS.

THE RESPONSIBILITY AND DISPOSAL OF THE "HALF-INSANE" AND ALLIED QUESTIONS.

In the past few years an unusual amount of interest has appeared in the problem of the interrelation of vice, crime and insanity. In the numerous contributions to the subject practical suggestions have held a somewhat larger place than heretofore. Matters which especially appeal to the psychiatrist are the study of the criminal mind by the psychologist, the renewed discussion of the vexed question of the limits of responsibility for crime in "borderland" insanity, and the unanimous advocacy of special institutions for the care and custody of the offender or criminal of this type and the better protection of society thereby. Investigations have been made by several observers into the mental condition of criminals at the time of sentence and the need made evident of a psychiatric service in connection with tribunals and more thorough expert examination of prisoners generally.

Grasset [1] discusses the medico-legal aspect of crime committed by persons who, through genius, heredity, upbringing or trouble, are not wholly insane, and he refutes the theories forced upon the nation by antiquated legal restrictions that all persons are either crazy or not crazy, responsible or irresponsible. He establishes a middle class, which, he states, has never yet been recognized by society; a class which society must treat, and against which society must protect itself. The half-insane exist. It is equally erroneous to class them either with the insane or with the sane. They are different from the sane in that they are psychically afflicted, and from the insane in that they preserve a certain degree of reason. He mentions an interesting list of geniuses, including authors, musicians, reformers of his own and other European countries, whom he considers, as did Nordau, not wholly sane. But whereas Nordau unjustly grouped them all with the insane, he more exactly defines their position as "demifous." As to their responsibility, when a "demifou" has committed a crime he has become injurious to society. He is dangerous. Society still owes him assistance and treatment, but it also has a right to defend itself against his misdeeds. For him, one must not choose either a prison or an asylum; he needs both. He believes in shortening sentences, special regimen and penitentiaries, special surveillance and treatment after one sentence, and a special institution, or at least a special section of some institution, for the "demifous," or half-insane.

Marandon de Montyel [2] emphasizes the distinction between the criminal lunatic, the insane criminal and the perverse, the latter plainly belonging, it seems to us, in another class of demifous,—the morally insane. The first commits his crime on account of his insane condition, the second is criminal at the start and later becomes insane, while the third is not properly to be considered as insane at all, his memory, reason and judgment being sound, his deficiency presenting itself in the moral sphere alone. Each of these classes of cases requires different treatment, and it is an injustice to each to keep them together as has been done heretofore, and is to a large extent still the practice. The study of the third class, the perverse and their management, is most important. They are the terror of asylums. They know perfectly well their rights, that they are not insane, and are only through an injustice confined along with the insane, though they are ready enough to use the asylum as a place of refuge and support, especially through the inclement season of the year. By their egotism, their quarrelsomeness, their insubordination and ability to evade the rules, to fashion keys and weapons, and by their bad influence over the other patients, they keep the institution in constant turmoil, and through the reckless carrying out of their schemes are a source of danger, though their crimes do not so generally take the form of violence, as of swindling, malicious mischief, and mean and dirty tricks. They are, he considers, not mentally deficient — an opinion which is open to question — and are capable of education, but the defect in moral control is congenital and can rarely be overcome. They differ in all particulars from the ordinary insane, criminal or otherwise, but while the good of the community demands that they be sequestered they should be provided for in special institutions, which should be constructed strongly enough to prevent their escape, and in which there should prevail a discipline more rigid than in an ordinary asylum, and yet less strict than in a prison. Here they should not only be cared for but should be taught trades of some sort, and given such moral training as possible. Into these institutions they need not be committed for life, but in the interest of the community their discharge should be hedged about with such precautions as to insure that their condition is sufficiently improved to make it unlikely that they will continue to be a danger to the public. The author discusses at some length the general plan of such an institution, and the legislation on the subject which he thinks is needed.

Morel [3] makes an earnest plea for the thorough and individualized study, by trained psychiatrists of all cases of habitual criminals, the great majority of whom are afflicted with mental

[1] Demifous et Demiréponsables: Par Grasset, 1907, and Jour. Nerv. and Ment. Dis., November, 1907.

[3] Morel: Jour. de Neurol., xi, 12, 1906, and Jour. Nerv. and Ment. Dis., February, 1907.

defect, more or less pronounced. Also, for the establishment of institutions for the medical care and training of such individuals. The author insists upon the inutility of punitive measures in cases of this character, and believes that better results are to be expected by medico-pedagogical methods.

Toulouse and Crinon,[4] discussing the problem of responsibility, do not undertake to define the nature of crime or of the social reaction against it, though on this point they seem to be in harmony with the modern positivist school, and they remark that the protection of society is much better guaranteed if, instead of regarding "punishment" as a method of correction, we regard it as "above all a measure of treatment." As responsibility is based on lucidity of consciousness and capacity for voluntary effort, which vary as we pass from normal to abnormal individuals, punishment (if the word is still to be used), to be just, must vary correspondingly, according to the psychological conditions. Thus it comes about that the medical expert is asked to decide the state of an individual's "responsibility." At this point there is a division of opinion. Some authorities assert that the idea of responsibility is not a medical or even a scientific conception; that the medical expert who expresses an opinion on this matter is going beyond his own field, since he is only justified in stating the actual medico-psychological facts which he can find in the individual presented to him. The authors do not share this opinion, but assert that the problem of penal responsibility is a psychological problem, and the recent investigations into the attitude and power of the criminal mind undertaken by Münsterberg and other psychologists lend color to their view. The current methods of psychiatrical observation, the authors declare, are altogether insufficient, being superficial, narrow and involving no elements of exactitude. It is by the systematic application of experimental methods that we can alone learn precisely how far an individual is abnormal in intelligence and aptitude for voluntary effort, how far he is capable of education, and what treatment he requires. Italy, the authors believe, is now leading the way along these paths, and they refer especially to the medico-legal methods used by Tamburini.

A purely psychiatric preparation no longer suffices to equip an expert in this field, the author concludes. It is necessary, but is not sufficient; familiarity with the methods of the psychological laboratory is also required. This is all the more important since criminals must not be divided beforehand into vicious and insane. Every inculpated person should be examined by an expert. This is necessary not merely to discover those who are, in the ordinary sense, insane, but for the more difficult and important end of ascertaining how far those who are not technically insane are susceptible of medico-psychological treatment. The authors incline to think that all criminals should receive sentence (although their actual presence in court might in some cases be dispensed with); for it is for the judge, representing society, to determine what persons are, in their present condition, unfit for society; but for all serious offences the indeterminate sentence is the only one that should be permitted. In all cases, also, there should be a preliminary period of observation before the method of treatment is decided and the offender classed. The prison must be a hospital. The medical expert, however, should remain only an expert, and it would be for the judge to sanction or not his recommendations. Not all these ideas, the authors remark, are yet realized, but they are meeting with less and less opposition and it is becoming generally recognized that simple criminals and insane criminals are not essentially different.

A report made at the recent Lisbon Congress of Medicine gives us Van Hamel's[5] views as to the aims which should guide the administration of penal reform, and they are in many respects similar to those of the French collaborators. The object of penal reform should be the diminution of crime. This is an end at once practical and realistic, and should not have as its point of departure any dogmatic religious, philosophical or ethical system. The object should be to decrease the number of criminals, not to increase the number of those punished. The combat against crime should be regulated by scientific study of its causes,—criminal etiology. These causes are general and personal. The general causes are mainly social; the personal causes, anthropological. Penal justice should dispense measures of social education to corrigible, measures of social protection to incorrigible, criminals. The distinction between young and adult criminals is of less value than one based upon psychological state, social needs, and to what extent they are in danger to the community. Much latitude should be left to the judge in the choice between a number of educational and protective measures. In order to assist him to make a proper choice, a psychiatric service should be attached to each tribunal and to each correctional establishment.

This recommendation of Van Hamel is among the reforms advocated earlier by Colin and Pactet in their conjoint monographs on "Les Aliénés devant la Justice" and "Les Aliénés dans les Prisons," based on extensive investigations of the prisons and judicial methods of France. They are convinced that the only effective means of avoiding the imprisonment of the insane as convicts would be the examination of the accused by an alienist on his arrest as the first step in every criminal case. This opinion which, they admit, may seem a utopian idea to-day will be accepted as a matter of course to-morrow.

A Psychiatrical Clinic in Brooklyn.— Dr. O. M. Dewing, superintendent of the Long Island State Hospital, announces that a psychiatrical clinic will be held at the hospital, every Friday at 9 A.M. Interesting cases will be presented at the clinic, and an opportunity given for examination of these cases and a general discussion.— *New York Med. Jour.*

Reports of Societies.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

THIRTY-THIRD ANNUAL MEETING,
HELD AT COLUMBUS, OHIO, OCT. 8, 9 AND 10, 1907.

(Concluded from No. 22, p. 734.)

THE RELATIONS BETWEEN THE MEDICAL PROFESSION AND THE PEOPLE.

PRESIDENT H. H. GRANT spoke on this subject. He said that we all realized that the world was full of wretchedness, deformity and disease; that this was due to ignorance and cupidity, distributed well over the whole population from rich to poor. All realized the measures of relief must be a slow and gradual reform, conducted by a concentration of many influences, wielded by society at large. All realized the obstacles to success, as well as the possibilities of abuse in the methods, and all knew the need of a directing influence which was thoroughly informed and could be confidently intrusted with power. It was his belief that through the trust and the support of the general public, given to a conscientious medical profession, disinterested as a body, with identical concerns with the public, a highly comforting progress would soon be recorded. With a view to the hopeful advance of these noble and world-rewarding benefactions, the profession of medicine, without jealousy or thought of self-interest, should devote its wisest and most faithful workers as chieftains; let the lay and the religious press, ever ready upon conviction as earnest and determined associates, with unremitting zeal uphold and champion the cause, and add to this the patient and never-failing confidence of a liberal and trusting general public rallying its invincible support, and there would open up before the coming generation such a prospect of achievement and victory as would be a soul-satisfying record.

NEURASTHENIA GASTRICA.

DR. CLEMENT R. JONES, of Pittsburg, reported four cases of this condition, and concluded that neurasthenia gastrica or nervous dyspepsia was frequently due to or complicated by eyestrain; that other gastric disturbances were sometimes aggravated by eyestrain; that along with other points in the examination of gastric cases this should not be neglected. When eyestrain was the cause of gastric symptoms the relief by proper refraction was prompt and satisfactory.

DR. R. D. CLIPPINGER believed that eyestrain often produced all the symptoms of an old so-called chronic gastritis. The general practitioner was apt to ignore the eyes.

DR. MARK D. STEVENSON found that very many patients were relieved of nausea and vomiting by the wearing of proper lenses.

DR. GEORGE P. SPRAGUE said that so-called gastric disturbances in neurasthenia were very often roundabout reflex disturbances due to vertigo; in one case a lack of equilibrium due to a visual defect; in some other case not. He found very commonly in sending neurasthenics to oculists for the correction of eyestrain that until the attention of the oculist was called to the possible psychic connection between the patient's condition and the visual defect, he very often failed to give the correction, which he could and did do after that had been called to his attention.

REINFECTION WITH SYPHILIS.

DR. A. U. WILLIAMS, of Hot Springs, Ark., had seen a number of cases in which he had suspected reinfection. In many the history of the first attack was indefinite and unreliable. In but very few cases was the history sufficiently plain to make anything like a positive diagnosis of a second attack. He cited two cases in which the symptoms and history were so plain that he thought he could safely claim both as cases of reinfection.

TOXEMIA FROM THE STANDPOINT OF PERVERTED METABOLISM.

DR. RALPH W. WEBSTER, of Chicago, Ill., concluded that toxemia, aside from that following the acute or chronic bacterial processes, was always of metabolic origin. The toxemias under discussion were more the effects of a general metabolic perversion than of a direct organic disorder. A specific toxemia, in the sense that it was due to a specific substance, was unknown in the class of toxemias treated.

DR. THOMAS HUNT STUCKY, of Louisville, Ky., followed with a paper in which he discussed auto-intoxications of intestinal origin which resembled typhoid fever.

THE TREATMENT OF SCARLET FEVER AS A STREPTOCOCCUS DISEASE.

DR. J. E. COLEMAN, of Canton, Ill., had treated this disease with carbolic acid internally and externally, together with small doses of aconite, the first few hours until fever was allayed. In all of the cases he had thus treated the disease was materially shortened, the rash rapidly faded, and on the second day the fever disappeared and the throat symptoms were also relieved. When this treatment was used, there was not any desquamation of the skin, nor any after-effects from the disease, such as nephritis, or discharge from the ear. He had successfully treated cases of scarlet fever by the application of the two remedies mentioned since the time of an epidemic of the disease, year after year, admitting, however, that the results obtained might possibly have been due to the fact that the disease ran a benign course.

RELATIONS OF THE DOCTOR TO THE ALCOHOLIC PROBLEM.

DR. T. D. CROTHERS, of Hartford, Conn., showed the intimate associations of alcohol with a large part of the mortality, disease and degeneration of the present time, and urged the profession to take up the physical study of the subject. He showed that the mortality from alcohol, both direct and indirect, was from 10% to 20% of all deaths, and at least 10% of all diseases were very largely influenced and due to this cause; also that from 20% to 50% of all mental diseases and 50% of idiocy, pauperism and other degenerative conditions had an alcoholic causation. Fifty per cent of all criminals serving sentences for crime in 1906 were due to the influence of alcohol. Nearly half a million persons came under legal recognition for intoxication and petty crimes last year. Reliable authorities showed that 50% of all railroad and other accidents were due to the mistakes of persons under the influence of spirits. Beyond this the losses, the revolutions and injuries noted in every community assumed great proportions. This problem was a physical and medical one. Every advance in science showed that there were physical causes which developed from distinct sources which could be studied and known, and that the whole subject was not a mass of theories, but one of facts the same as that of epidemic and contagious diseases. The evils had reached such a stage that public opinion was making Herculean efforts along theoretical lines to overcome and break it up. The author urged that it was a medical subject to be understood by medical men. When the facts were studied

and known, the remedies and methods of prevention would be clear and practical. The failure of physicians to know the subject had brought in an army of gold cures and quacks whose presence was a reflection on the intelligence of the physician who understood and treated these people. The great temperance movement should be directed and managed by physicians along exact lines of scientific study, above all prejudice; then they would become practical, and reach to the bottom of the great drink problem and point out the methods of cure and prevention. When medical men were taught to recognize the physical side of this problem and study the facts alone, irrespective of all theories, then the mortality and disease would disappear.

THE RECOGNITION AND MANAGEMENT OF ACUTE MASTOIDITIS BY THE GENERAL PRACTITIONER.

Dr. Leartus Connor, of Detroit, Mich., in a paper on this subject, drew the following conclusions: (1) Cases of acute mastoiditis should be regarded as seriously ill, placed in bed, given a brisk cathartic and diaphoretic, and the diet limited to at least one half. (2) If there be present tenderness of the mastoid, redness and bulging of the inner, upper and posterior external auditory canal and adjacent membrana tympani, Wilde's internal incision should be promptly done. (3) Regular irrigation with water, as hot as could be endured, should precede and follow the incision, and dry heat follow during the interval of irrigation. (4) An aseptic should be applied to the wound after each irrigation; a 50% solution of argyrol on a cotton-tipped probe was convenient and useful. (5) Thus managed, many cases of acute mastoiditis would speedily recover. (6) If they grew worse steadily, the mastoid should be promptly opened, all diseased tissues removed, and the wound dressed aseptically. (7) A painful deaf ear merited quite as careful attention as a red painful eye, or a painful stiff limb. Until this be accorded it, physicians would continue to have cases of extensive destruction of mastoid bones, permanent loss of hearing, infection of lateral sinus, facial paralysis, subdural, cerebral, and cerebellar abscess, and death labelled "the disease went to the head," and "the body to the boneyard."

MORPHINE ADDICTION.

Dr. George P. Sprague, of Lexington, Ky., discussed some of the essential points in the etiology, pathology and treatment of those addicted to morphine. He divided the cases into three groups: First, a small one composed of normal individuals, who from unwise treatment for pain in acute illness had contracted the habit. A second larger group of moral degenerates who indulged in the vice of morphinism, and a third, and much the largest group, recruited from among the neuropathic weaklings, from the victims of improper training and lack of early discipline; from the vast army of defectives, who, beginning to lose ground in the race of life, resorted to drugs as a spur, and from the large number who, suffering from sudden shock of disease, loss, etc., resorted to the drug in the hope of obtaining relief.

These patients should be under treatment for months; that the patient should not be alone a moment when he might procure morphine, day or night; that every one coming in contact with him must be above bribery, and that his nurse must be above suspicion, and ever suspicious. The patient's sense of right and power of will should be steadily stimulated, and every physical ill he might have should be found and vigorously combated.

THE NATURE OF MORPHINE DISEASE.

Dr. Chas. W. Carter, of Richmond, Ind., said that the physician who would understandingly and conscientiously treat the morphine disease must have a generous breadth of view in reading human character, an entire want of prejudice in interpreting symptoms and a broad and thorough knowledge of remedial agents.

MEDICAL INSPECTION OF PUBLIC SCHOOLS.

Dr. Frank W. Gavin, of Canton, Ohio, said the medical inspector should look after, first, the school building, its condition, ventilation, lighting, heating, seating, etc. Second, the inspection of candidates for teachers' certificates in the principles of preventive medicine and school hygiene. Third, physical and mental condition of the child.

He pointed out the advantages of medical inspection and the methods of examination. The salary of a medical inspector should be generous, thus warranting the selection of the best men procurable. He sincerely believed it would be money wisely invested on the part of cities and municipalities.

URINARY INFECTIONS IN CHILDREN.

Dr. I. A. Abt, of Chicago, Ill., pointed out the avenues through which micro-organisms gained access to the bladder and to the pelvis of the kidney in these infections. Bacteria might enter the bladder through the urethra and migrate upwards to the bladder and thence to the kidney. The infection might be hematogenous in character, the micro-organisms finding access into the bladder through the blood vessels. The micro-organisms might pass in some manner from the bowel through the loose cellular tissue of the pelvis into the bladder. The fact that sometimes a bowel infection, particularly follicular enteritis, preceded an attack of cysto-pyelitis, had suggested this view. Congenital malformation of the bladder and kidney predisposed to cystitis and pyelitis. Such a case had come under his observation. This was given in great detail. He described the symptoms and course of the disease.

With reference to treatment, the ordinary urinary antiseptics in one form or another used internally would usually bring about the desired result. In the severe forms of streptococcus or staphylococcus infection the vesical irrigation might be indicated. In other respects the treatment was purely expectant and symptomatic. The pain and restlessness might require the use of antispasmodics and sedatives.

The following papers were likewise read: "The Profession of Medicine, as it Was, and as it Is," by Dr. Robert Barclay, of Pittsburg, Pa.; "Purulent Conjunctivitis in Infants and Adults," by Dr. Mark D. Stevenson, of Akron, Ohio; "Gelseminine," by Dr. Wm. F. Waugh, of Chicago, Ill.; "Colorado and the Eastern Pulmonary Case," by Dr. W. A. Campbell, of Colorado Springs, Colo.; "Pregnancy when Complicated by Tuberculosis," by Dr. Harold A. Miller, of Pittsburg, Pa.; "The General Practitioner's Attitude toward Eyestrain," by Dr. Richard D. Clippinger, of Bellefontaine, Ohio; "Gallstones as an Etiological Factor in Diabetes," by Dr. J. C. O'Day, of Oil City, Pa.; "A Résumé of Gallstone Factors," by Dr. R. Alexander Bate, of Louisville, Ky.; "The Psychasthenic States," by Dr. Chas. W. Hitchcock, of Detroit, Mich.; "What we Learn from Analysis of the Feces," by Dr. Joseph A. Sweeney, of Louisville, Ky.; "A Contribution to the Literature on the Pathology, Etiology, Symptomatology and Technic of the Operation of Supravaginal Hysterectomy for Fibroid Tumors of the Uterus," by Dr. Frank D. Smyth, of Memphis, Tenn.

OFFICERS.

The following officers were elected for the ensuing year: President, Dr. Arthur R. Elliott, of Chicago; Vice-Presidents, Dr. F. F. Lawrence, of Columbus, Ohio, and Dr. Robert C. McChord, of Lebanon, Ky.; Secretary, Dr. Henry E. Tuley, of Louisville (re-elected); Treasurer, Dr. Samuel C. Stanton, of Chicago (re-elected).

The 1908 session will be held in Louisville in October.

Book Reviews.

Practical Physiological Chemistry. By PHILIP B. HAWK, M.S., Ph.D., Demonstrator of Physiological Chemistry in the Department of Medicine of the University of Pennsylvania. Philadelphia: P. Blakiston's Son & Co. 1907.

This work on physiological chemistry is a comprehensive one and is unusually complete and yet at the same time practical. The author has presented some of the subjects in a rather different manner from that ordinarily found in books of this kind, and this is particularly true in connection with the treatment of food stuffs and their digestion.

Considerable attention has been given to the examination of feces for purposes of diagnosis; also to the subjects of epithelial and connective, muscular and nervous tissues.

Many of the illustrations are original and some are excellent. The work is certainly a credit to the author.

A Short Practice of Medicine. By ROBERT A. FLEMING, M.A., M.D., F.R.C.P.E., F.R.S.E., Lecturer on Practice of Medicine, School of the Royal Colleges, Edinburgh; Assistant Physician, Royal Infirmary, Edinburgh. Philadelphia: P. Blakiston's Son & Co. 1906.

"The writing of a new book on the practice of medicine demands an apology, or at least an explanation." So the author begins his preface. It is the duty of the reviewer to determine whether the author's explanation justifies the book or not. In doing this, fairness requires that the book be considered within the limitations set by its author. These limitations are that the book should be small and so adapted for use in the class-room. It is intended mainly to be used in this way, as a general outline in connection with cases in the clinic and in preparation for examinations. It is a short practice of medicine and it does not contain descriptions of clinical laboratory method.

The reviewer does not believe there is much need for such a book, because the larger textbooks in one volume contain far more information, are not greatly more bulky (this volume is in no wise a pocket edition) and cost but little more. To obtain a smaller volume, omission and condensation are necessary, whereas as a matter of fact, in the larger single volume textbooks this process has been carried already dangerously near the limit. Granting, however, that there is some need for such a small textbook and recognizing the necessity for much selection as to what should be described with each disease, it remains to be determined how well the book has been made under these conditions.

Those portions which treat of diseases of the various systems,— respiratory, circulatory, nervous, etc.,— have been condensed in a fairly satisfactory manner. The specific infectious diseases have not been handled so well, and here a number of statements are met to which exception can well be taken. The space given to the classification of fevers might better be devoted to something else since the classification used is both loose and antiquated. The discussion of the general treatment of fever is too discursive and indefinite to harmonize with a book in which brevity is a prime object.

In discussing typhoid fever the impression is given that cicatrization of the ulcerated gut is an important process, whereas we know that usually the ulcers heal so perfectly that in a short while there is but little to indicate a previous lesion. The Widal reaction is described twice within six pages, an unnecessary repetition, and unfortunately the method given the second time differs somewhat from the first. Under "isolation of bacillus" no mention is made of blood cultures, and splenic puncture is given as the best method. Diet, the all-important factor in treating typhoid, receives but scant attention.

Confusion may arise in the student's mind when an organism is spoken of in one place, as the Klebs-Löffler bacillus, and in another, as the Löffler bacillus. Such an instance is an example of what occurs in several places and indicates a lack of careful editing. "A continuous spray of steam . . . upon the patient's face," if followed to the letter by the student, would surely lead to dire result, yet there is nothing to indicate what is meant by this therapeutic suggestion for the treatment of diphtheria. In describing the cultural characteristics of the influenza bacillus, the necessity of the presence of hemoglobin in the culture media is not mentioned.

Too much importance apparently is attached to the presence of the pneumococcus in the sputum as a diagnostic point in pneumonia, and many would not agree with the direction, "never let the patient sit up," as best for all cases of pneumonia. All of the points here criticised are in that part of the book which deals with the infectious diseases, and much of this might readily be improved in subsequent editions.

In the other parts of the book some mistakes occur, but they are infrequent and the statements given are for the most part acceptable. The book itself is well printed and in general well written. The reviewer believes that the attempt to make a short treatise on medicine is exceedingly difficult, and the present attempt is perhaps as successful as could be expected from any author. Why an author should be willing to plunge into these difficulties is not easy to see. Many, however, do take the plunge, and get into more difficulty than does Dr. Fleming.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 5, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

ADOLESCENCE.

SOME three years ago Dr. J. Stanley Hall produced an important work entitled as above. He now submits a briefer and perhaps more practical volume: "Youth, Its Education, Regimen and Hygiene,"[1] in which is contained the gist of the former book. The subject must indeed appeal to every experienced physician who has seen families grow up from infancy under his professional care, who knows of the aberrations which come about at the most difficult period of puberty.

Two great forces dominate life: Hunger, by which existence is maintained, and that force which is concerned in the perpetuation of the race. And the latter, at the beginning of its influence, is likely to be well-nigh destructive, both physically and to the psychism, if the organism has not been properly developed and educated for its reception. Dr. Hall's work is based entirely upon the principles of muscle culture and muscular development. Physical training is good not for the body alone; he believes that the very growth of the brain depends upon the growth and use of the muscular system, that mental and moral natures have developed as the accessory muscles have increased in number and have grown into use. In his belief human progress, indeed, lies in increasing the capabilities of both fundamental and accessory muscles. And it is these principles which Dr. Hall would apply to the regimen of the adolescent period. He gives also much attention to the needs of childhood between the seventh and the twelfth years. Several chapters in this valuable book (doubly valuable because of its detailed descriptions and directions) set forth the respective advantages, methods and results in muscular training and in physical, mental, and moral development, of industrial education, manual training and sloyd, various systems of gymnastics and of play, sports and games. Herein we see justified those university authorities who encourage athletics in their students, lest worse mischief befall them.

Dr. Hall is not a medical man; he is a psychologist. Some dozen years ago he began to deliver lectures upon adolescence from his viewpoint. Soon friends and strangers alike approached him for guidance of their offspring, who were in or near this critical age. The interest in his work grew, until at one time more than twelve hundred letters were on file in his office from parents anxious concerning the development and welfare of their children. He began to realize that had he been a physician he might have found himself with a large practice from such cases. All kinds of questions, some of them quite impossible, are asked him about young people, "who are bright, geniuses, dullards, born short, one-sided in their mental, physical or moral development," etc. Some letters "contain long and pitiful tales of obvious ignorance, misunderstanding, wandering from doctor to doctor, and getting no relief and no insight." Wherefore Dr. Hall concludes, and the suggestion may be worthy the attention of physicians desirous of embarking upon a special work, that as gynecology and pediatrics have become specialties, there is now place for another specialty, in the treatment of adolescent affections of mind and body. Only let no colleague undertake this task who cannot comprehend the maxim of Hippocrates: "God-like is the physician who is also a philosopher."

[1] Messrs. Appleton & Co., publishers.

THE COLLECTIVE INVESTIGATION OF DISEASE.

A NOTABLE tendency during the past few years has been the increase of co-operative work in the investigation of medical problems. The work of the individual investigator is more and more being carried out with reference to others, and often in definite co-operation. The general enthusiasm regarding the tuberculosis problem, painstaking investigation by groups of men of the etiology of cancer, the tendency, in general, to enlist the interest of all working on the same subject, is everywhere apparent. The usefulness of such a method cannot be questioned, as we have had occasion to point out on various occasions. Medical problems of the future are likely in great measure to be solved by the combined

efforts of many persons working toward a given end, but from different points of view. The promise, for example, in such an establishment as the Carnegie Institute for Medical Research lies not so much in the fact that this man or that is pre-eminent as an investigator, but rather that there are gathered together under one roof many investigators pursuing their researches from more or less different points of view, but with a common purpose.

Recent examples of this salutary tendency toward co-operation is shown by the attempt which is now going forward to obtain comprehensive statistics on the disease poliomyelitis, now so prevalent, and to subject these statistics to the scrutiny of men especially qualified to determine the various questions which such statistics present. If, for example, the cerebrospinal fluid taken from a large number of cases and studied by the same methods shows nothing of significance, we may certainly rest assured that unless entirely new methods of investigation of this fluid are discovered, we may not hope for a solution of the problem of etiology from this source.

Again a permanent committee has recently been formed by the National Association for the Study of Epilepsy, composed of three men, whose interest in and knowledge of the subject is acknowledged, to act as an advisory board with the specific object of furthering the co-ordination of scientific and research work in epilepsy, and also to act as advisors to any workers in epilepsy who choose to apply to them. Here again such a concentration of authority in the hands of a few well-equipped men is sure to bring about the co-operation essential to the elucidation of the problem of epilepsy, to prevent waste of effort and repetition of work, and to afford the highest possibility of reaching results of positive significance.

Many other instances might be cited in which this principle of co-operation, varied to meet the different demands of the problem under consideration, might be applied with advantage. Such co-operative work could by no possibility interfere with personal initiative nor detract from the credit due to special investigators. The questions at issue are becoming so complex and are encroaching upon the domain of so many correlated sciences that future students must in great measure come to a candid acknowledgment of this fact, and accomplish results through adoption of methods of research, in which the co-operative element will be a predominant factor.

MEDICAL NOTES.

THE AMERICAN JOURNAL OF ORTHOPEDIC SURGERY. — The *American Journal of Orthopedic Surgery* has decided to add one or more monographs of not less than twenty pages to its regular one hundred and thirteen pages of practical papers and fifteen pages of abstracts of orthopedic literature in every number.

The *American Journal of Orthopedic Surgery* is the only periodical in the English language devoted exclusively to Orthopedic Surgery and borderland subjects. There are three published in Germany, one in France and one in Italy.

FEAR OF PREMATURE BURIAL. — The *Lancet* states that about a month ago a London newspaper chronicled the fact that a woman on the Continent had been buried with a loaded revolver in her hand ready to end her existence should she subsequently in her coffin become cognizant of her surroundings.

A POSSIBLE CURE OF LEPROSY. — It is reported that the Board of Health of Honolulu, on the petition of a large number of lepers at the Molokai settlement, have issued a permit to J. Lore Wallach, who claims that he has a method of cure, to treat twelve lepers from the settlement.

CENTENARIANS. — The following persons are reported to have lived upwards of one hundred years: W. R. Chambers, supposed to be the oldest resident of Pennsylvania, died Nov. 24, in Pittsburg, at the age of one hundred and five years, remaining in possession of his faculties to the end of his life.

Mrs. Vannelia Hull has recently died at the age of one hundred and one years, also in Pittsburg. She had lived in and about that city for ninety-five years, and is reported to have seen the first steamboat in that region and also the first coal taken from the mines of Pennsylvania.

Probably the oldest woman in Massachusetts, Mrs. Sarah Ingalls, died at Winthrop recently at the reputed age of one hundred and five years. She was born in Ipswich, June 30, 1802.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Dec. 4, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 67, scarlatina 43, typhoid fever 8, measles 23, tuberculosis 33, smallpox 0.

The death-rate of the reported deaths for the week ending Dec. 4, 1907, was 18.65.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Nov. 30, 1907, was 201, against 167 the corresponding week of last year, showing an increase of 34 deaths and making the death-rate for the week 17.20. Of this number 101 were males and 100 were females; 198 were white and 3 colored; 123 were born in the United States, 76 in foreign countries and 2 unknown; 47 were of American parentage, 126 of foreign parentage and 28 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 66 cases and 3 deaths; scarlatina, 49 cases and 0 deaths; typhoid fever, 10 cases and 0 deaths; measles, 25 cases and 1 death; tuberculosis, 44 cases and 24 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 30, whooping cough 0, heart disease 31, bronchitis 8 and marasmus 1. There were 10 deaths from violent causes. The number of children who died under one year was 29; the number under five years, 39. The number of persons who died over sixty years of age was 60. The deaths in public institutions were 65.

There was 0 cases and 1 death reported from cerebrospinal meningitis during the week.

Bequests. — By the will of Ann Thomas, the Holy Ghost Hospital for Incurables in Cambridge receives the sum of $500. By the will of the late Frederick Tompkins, of Newport, R. I., the Newport Hospital receives $2,000. The Lynn, Mass., Hospital receives $5,000, through the will of the late M. A. Fenton of that city.

Dr. Harvey W. Wiley, a Speaker at the John Harvard Celebration. — Dr. Harvey W. Wiley, of Washington, was one of the speakers at the recent celebration of the three hundredth anniversary held in Cambridge, of the birth of John Harvard, at the invitation of President Eliot. The subject of his address was "The Food and Drug Law."

A Lecture by Dr. W. T. Grenfell. — It is announced that Dr. W. T. Grenfell, widely known for his missionary and medical work in Labrador, will give a lecture at the Harvard Union in Cambridge, Dec. 10. His coming will be of particular interest this year, because of the recent completion of an endowment of $1,500 of a bed in one of his hospitals.

Another Leper for Penikese Island. — After a careful study of Bertha Osis, extending over two months, who was suspected of leprosy when she presented herself at the Massachusetts General Hospital, the diagnosis has finally been confirmed and she has been removed to the leper colony at Penikese Island. The bacilli of leprosy have repeatedly been demonstrated while she has been under observation.

Opening of Massachusetts Hospital School for Crippled and Deformed Children. — A portion of the building of the Massachusetts Hospital School for Crippled and Deformed Children at Canton was opened this week. It is estimated that the buildings will accommodate three hundred patients, and the effort will be made so to conduct their education that they later may become self-supporting. The location of the hospital, on the borders of the Blue Hill Reservation, is an exceptionally favorable one for its purpose. The superintendent is Dr. J. E. Fish, a graduate of the Dartmouth Medical School, and a man of experience in the administration of charities. Although the school is primarily a state charity, nevertheless the trustees, of whom Dr. Edward H. Bradford, professor of orthopedic surgery in the Harvard Medical School, is chairman, have power to admit paying patients. A chief aim of the institution, following modern philanthropic ideas, is to make the inmates, so far as possible, self-supporting.

Meeting of Massachusetts Medical Benevolent Society. — The annual meeting of the Massachusetts Medical Benevolent Society was held at the Boston Medical Library at 5 P.M., Oct. 31, the president, Dr. James C. White, in the chair; fifteen members present. The reports of the secretary and treasurer were read and accepted; that of the latter showing the par value of the invested funds to be $60,925 and the number of beneficiaries 14. The following officers were elected: President, Dr. James C. White; Vice-President, Dr. George W. Gay; Treasurer, Dr. W. L. Richardson; Secretary, Dr. W. H. Prescott, 285 Marlborough Street. Trustees to serve for three years: Dr. Vincent Y. Bowditch, Dr. Henry Jackson, Dr. Hardy Phippen. The following extract, from the Act of Incorporation, will show the objects of the society: "For the purpose of affording pecuniary assistance to members of the medical profession, their widows and children."

NEW YORK.

For Medical Research. — Announcement has just been made of an additional gift of $2,000,000, by John D. Rockefeller, to the Rockefeller In-

stitute for Medical Research, which brings the aggregate of his contributions to this cause up to $3,800,000. In his letter to the directors, stating his intention, Mr. Rockefeller expresses his gratification at the results thus far achieved by the Institute and his confident anticipation that the enlargement of its scientific work now made possible will lead to increased success in the future.

A CENTENARIAN. — Mrs. Margaret Horn died in the New York City Home for the Aged and Infirm on Blackwell's Island, on Nov. 27, at the age of one hundred and two years, having been born in County Cork, Ireland, in 1805. Her husband, Alexander Horn, is stated to have been one hundred and three at the time of his death, twelve years ago.

DIMINISHED MILK APPROPRIATION. — It is to be regretted that the Board of Estimate and Apportionment saw fit to cut down the milk appropriation for 1908 from $353,680, the sum asked for by President Darlington of the Health Department, to $68,580, and the Mayor's Milk Commission, composed of prominent physicians, has not hesitated to express the opinion that in so doing the city authorities have practised an unwise economy, since by providing stricter inspection they could undoubtedly have reduced the death-rate and the amount of disease. The Commission had recommended that the 25 inspectors for the country districts should be increased to 125, which would have permitted each farm furnishing dairy products to be visited about every six weeks, and that the New York City inspectors be increased from 15 to 40. The sum granted, however, will provide for but 10 additional inspectors, 8 for the country and 2 for the city.

A PARISH CONSUMPTIVES' CLUB. — Among the numerous philanthropic organizations maintained by St. George's Episcopal Church is the somewhat novel one of a Parish Consumptives' Club. In the parish are a certain number of young men and women suffering from tuberculosis, and some of these are unable to obtain adequate work and need financial assistance. All such it is proposed to care for, and while persons not belonging to the parish may join the club if they so desire, they are required to pay dues and the offer of financial aid is not held out. The great purpose of the club is stated to be not eleemosynary, but to encourage young people with pulmonary trouble to consult a physician and to promote among the members a cheerful frame of mind by inducing them to think of something besides themselves. To this end a variety of diversions are provided, while at the same time some measure of medical supervision is supplied, with advice as to the use of remedies and proper moods of living, with the services of skilled nurses in cases requiring them.

A TRIBUTE TO THE LATE DR. RICHARD H. DERBY. — At the last meeting of the Medical Association of the Greater City of New York, a committee, whose chairman was Dr. C. Cole Bradley, which had been appointed to prepare a suitable minute on the death of Dr. Richard H. Derby, presented its report. In the course of it the following tribute to Dr. Derby's public services was made: "He was an exceedingly public-spirited man, giving his time freely to every cause which he considered useful to the city and which had any demand upon his services. He was consulting ophthalmologist to the Health Department of New York City for many years, and in that capacity he became deeply interested in the ocular welfare of the children of the public institutions and of the public schools. In 1886 he brought to the attention of the Academy of Medicine the appalling prevalence of contagious ocular diseases in the public institutions for children and insisted on the need of legislation. After an exhaustive examination of the children by a committee composed of Fellows of the Academy, the law desired was drafted and passed. Later he brought before the Health Board the imperative necessity of caring for the eyes of the school children, devising ways and means for combating and treating the disease, then so prevalent amongst them. No greater charity has been performed by any man than this safeguarding and preservation of the vision of the orphans and waifs of our city and of our school children."

CELEBRATION OF SIXTIETH ANNIVERSARY OF THE NEW YORK ACADEMY OF MEDICINE. — The sixtieth anniversary of the New York Academy of Medicine was celebrated on Nov. 29. On the platform, in addition to the President, Dr. John A. Wyeth, were six ex-presidents of the academy, Drs. A. Jacobi, D. B. St. John Roosa, Wm. H. Thomson, Robert F. Weir, Edward G. Janeway and Charles L. Dana. The feature of the evening's exercises was an address by Col. W. C. Gorgas, of the Army Medical Service, chief sanitary officer of the Isthmian Canal Commission, which was illustrated by means of stere-

opticon views. In the course of it he said that when the United States commenced the great engineering work of making the Panama Canal, Colon and the city of Panama were as unhealthy as Havana before yellow fever was practically eradicated there by an efficient system of screening, draining and sanitation through cleanliness. The negroes seemed to resist the dangers of infection, but visiting whites fell an easy prey to the attacks of the inoculating mosquito. The government had devoted $2,000,000 to making the canal zone healthy, and to-day yellow fever had been annihilated, while malaria, though it still existed to some extent, had been very materially diminished. A reception and collation followed Colonel Gorgas's address.

Obituaries.

EDMUND S. F. ARNOLD, M.D.

Dr. Edmund S. F. Arnold, of New York, died at Jacksonville, Fla., on Nov. 22, in the eighty-eighth year of his age. His active professional career was principally passed at Yonkers, on the Hudson, where for many years he was one of the leading practitioners of the town. During this time he was the attending physician to the large Mount St. Vincent Academy, and he took great interest in gathering an unusually fine mineralogical collection, which he presented to that institution. Nearly twenty-five years ago he retired from practice and removed to New York. Here he engaged actively in society work, and he was one of the original members of the New York County and State Medical associations. For a time he was the treasurer of the former of these, and for a number of years the librarian of the State Association. In this capacity he spent almost his entire time in fostering the interests of the new library, and did monumental work in the way of arranging, cataloguing, etc. The library was started soon after the organization of the association, in 1884, and in 1888 it was enriched by the fine private library, consisting of about 1,700 volumes, of Dr. Isaac E. Taylor, which was presented by the owner. Quarters were given it in the Carnegie Library, and it remained there until May, 1890, when it was moved to the Mott Memorial Building; after which it was maintained in connection with the Mott Memorial Library. By the time of its removal the library had increased to over 8,000 volumes, of which nearly 7,000 were bound books. Of late years Dr. Arnold had spent all his winters in Florida.

GEORGE F. SHRADY, M.D.

Dr. George F. Shrady, the New York surgeon and medical writer, died on Nov. 30, from pneumonia, with complications, after an acute illness of two weeks. For some time past, however, his health had not been good, and he had practically retired from professional work. Dr. Shrady was born in New York City, where his family had long resided, on Jan. 14, 1837. Both his grandfathers served in the Revolutionary War, and his father in the War of 1812, while he himself was a surgeon in the Federal Army during the Civil War. He was graduated from the College of Physicians and Surgeons, New York, in 1858, and in that year was awarded the Wood prize for proficiency in anatomy. He became widely known as a surgeon, and among his patients were many of the prominent men of the past generation. He was one of the principal attendants of General Grant in his last illness; he was consulted by Sir Morrell McKenzie in the case of the Emperor Frederick, of Germany, and he was also one of the consultants after President Garfield was shot. He contributed constantly to surgical literature and was long connected with various hospitals and other institutions as attending surgeon. At the time of his death he was consulting surgeon to St. Francis', the General Memorial, Columbus, Willard Parker, and Hackensack (N. J.) hospitals. He was also regarded as an authority on pathology, and for a number of years was president of the New York Pathological Society.

Dr. Shrady will perhaps be best remembered for his brilliant work as editor of *The Medical Record*, and this periodical remains as the most fitting memorial of his talents. Founded by him in 1866, it soon became known as one of the leading medical journals of America, and obtained a very wide circulation. He conducted the *Record*, with signal success, for no less than thirty-eight years, retiring from the editorship in 1904. The matter contributed to it by him would fill many volumes.

Dr. Shrady is survived by his second wife and several children. He also leaves a brother, Dr. John Shrady, ex-president of the New York County Medical Association. Both the latter's sons are physicians, and one of them is at present a city coroner.

ALEXANDER MACTIER PIRRIE.
A MARTYR TO SCIENCE.

A career of great promise has been cut short by the untimely death of Mr. A. Mactier Pirrie. The son of the late Mr. Alexander Pirrie, C. E., he was born on Oct. 2, 1882. He obtained his B.Sc. with honors in anthropology at Edinburgh University in 1904, and qualified as M.B., Ch.B., in 1906. He obtained the Carnegie Research Fellowship in anthropology and was appointed anthropologist to the Wellcome Research Laboratories at the Gordon Memorial College, Khartoum. He went out to the Sudan in the autumn of 1906.

Under the direction of Dr. Andrew Balfour, the director of the laboratories, Dr. Pirrie made his first expedition up the Nile to the southern

limits of the Sudan and penetrated to remote parts of the Bahr-el-Ghazal. His second expedition took him to the borders of Abyssinia. On both occasions he passed through some of the most pestilential regions of Africa in connection with certain anthropological and physiological researches, appertaining to tropical diseases, upon which the laboratories are engaged.

Unfortunately he contracted tropical fever (kala-azar) and was so prostrated as to be compelled to return to England, leaving Khartoum on June 17 last.

He rallied from the effects of the fever from time to time, but was compelled to enter Chalmers' Hospital, Edinburgh, in October. His death took place on Nov. 12.

He was interred at the Dean Cemetery, Edinburgh, on Nov. 15. The Gordon Memorial College, Khartoum, Sir William Turner, principal and vice-chancellor of the University, Mr. Wellcome and others were represented and sent wreaths. A resolution of sympathy has been conveyed to the relatives from the trustees of the Gordon Memorial College, and other expressions of sympathy have been received from the Liverpool School of Tropical Medicine, etc.

It is of interest to note that the first case of kala-azar found in Africa, except a case in Tunis, referred to by Laveran, was reported by Dr. Sheffield Neave, pathologist to the Wellcome Research Laboratories, Khartoum. Dr. Neave found the Leishman-Donovan body, the parasite of kala-azar, in the splenic blood of a patient in the Omdurman Civil Hospital. The discovery is noted by the director in the Second Report of the Laboratories.

Dr. Pirrie presented a paper on his African expeditions at the last meeting of the British Association for the Advancement of Science, but was prevented from being present on account of his illness. He brought back a most valuable collection of objects of scientific interest.

At intervals during his illness he was engaged on his report to the Carnegie Institute and the Wellcome Research Laboratories, Khartoum, for which institutions he acted jointly in the important work he carried out in the Sudan.

Current Literature.

NEW YORK MEDICAL JOURNAL.
Nov. 9, 1907.

7. HANLEY, L. G. *Extra-uterine Pregnancy.*
8. *BRADDOCK, C. S., JR. *Treatment of Snake Bites as seen in the Jungle.*

8. Braddock, formerly chief medical inspector of the Royal Siamese Government, states that the python or boa rarely attacks people. Two snakes, the hamadryad and cobra, cause an annual death-rate in India of about 22,000 people. The hamadryad will always attack a man on sight. Nearly all bites are received after dark, by stepping on snakes or by lying down with the snakes in blankets or clothing. The poisonous snakes leave only the two punctures of the poison fangs. Hence, the marks of teeth in snake bites make the prognosis favorable. The treatment must be immediate and strenuous. A tight tourniquet is applied above the bite, the tissues are freely opened, and pure crystals of potassium permanganate are rubbed into the wound. A strong solution of permanganate is injected all round the bite. Nitroglycerin, digitalis, alcohol and strychnia are given in large doses. This treatment instituted early will usually save life. Otherwise death is fairly certain. [R. I. L.]

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.
Nov. 9, 1907.

10. GARDINER, J. P. *A Case of Congenital Hour-Glass Stomach with Accessory Pancreas.*
11. GRIFFIN, O. A. *Ocular Symptoms of Nasal Origin.*

1. Patrick has treated sixteen cases of trifacial neuralgia with deep injections of alcohol. Although it is too early to judge of permanent results, the immediate results are most satisfactory. As a rule there is no recurrence after several months at least. Then the injection can be repeated. The technic preferred is that of Lévy and Baudouin, which is that advised by Hecht (2). The principle is that of infiltrating the branches of the fifth nerves at their exit from the skull, viz., the supra-orbital immediately after entrance into the orbit, the superior maxillary after its exit from the foramen rotundum, and the inferior maxillary after its exit from the foramen ovale. The injection of the supra-orbital branch seems liable to be attended with danger. The injection of the other two branches is apparently not difficult and Patrick has done them in his office. The real difficulty is to strike the nerve. It is not necessary to inject the nerve sheath itself, only to have the fluid infiltrate it. Failure to strike the nerve may relieve the neuralgia for a few hours or days, and requires further injections until successful. The needle employed is of special make. It is fitted with a blunt stylet, which is pushed home after the skin is pierced, so that a blunt instrument is used for penetration of deep tissues. The fluid used is 70% to 90% of alcohol with a little chloroform and cocaine. Two cubic centimeters is given as a dose. The pain of the injection is surprisingly slight. Anesthesia was given in only one case.

6. Contrary to the general belief, Morse finds that adenoids in infancy are very common and of greatest importance. They may be the cause of frequent colds, otitis media, cough, croup, convulsions, etc. Removal is simple and effects a cure. In a goodly proportion of cases the adenoids do not recur.

8. Recent excavations in Memphis, Egypt, have brought to light some representations in stone of surgical operations, probably dating back to 2,500 B.C. The interpretation is rather obscure. One operation is evidently opening a boil. Another seems to be a circumcision. A possible interpretation of a third is the breaking of a chordee. [R. I. L.]

1. Porter's personal experience in the observation and treatment of two cases of malignant skin lesions following exposure of the hands to x-ray significantly emphasizes the danger to members of the profession engaged in x-ray work. The early dermatitis has a marked tendency to lead to local epithelioma, which, in five of the ten cases previously reported in the literature, has been followed by fatal metastasis. Hence the pertinent conclusions as to the necessity of prompt and efficient treatment of such lesions by excision and grafting, or by amputation. There is an instructive pathological report by White, and a valuable description of the technic of skin-grafting, which Porter developed in the course of his study.

3. In connection with the above, it is appropriate to note the liablity of cutaneous horns to epitheliomatous degeneration and the consequent desirability of their radical removal.

7. Accidental injury to the thoracic duct is an occasional complication of deep operations on the left side of the neck. From an examination of the literature, DeForest concludes that this is not so serious a condition as one might fear; death as a result of it is rare, temporary disturbance of nutrition may ensue, function is generally restored through collateral channels. For treatment he recommends suture of the wounded duct, if possible; otherwise, ligation, suture of surrounding tissues, clamping, or tight pack.

9. Dwight presents an interesting anatomic study of ossification of the stylo-hyoid chain. Consideration of the embryology leads him to believe that such ossification is not a degenerative process of age, but the early conversion to bone of persistent fetal cartilage. This belief he illustrates by description of a series of cases, of which three are of his own recent observation. Clinically the condition may interfere with operations on the carotid arteries, the parotid and the tonsil; and it may cause difficulty in swallowing. Diagnosis may be made by bimanual examination and by x-ray.

10. Recent experiments in artificially produced dynamic ileus have called attention to the possible clinical importance of such a condition following operation. Bloodgood reports cases of acute post-operative gastric dilatation, a case of primary acute, and a case of chronic, gastro-mesenteric ileus, — all apparently physiologic in origin. He contrasts these cases with others of acute high mechanical obstruction, and suggests as points in their differential diagnosis that in the latter pain begins earlier and distention later than in dynamic ileus. For treatment of acute gastric dilatation he advises first the stomach tube, with knee-chest or left lateral position; if this fails, later operation; posterior gastro-jejunostomy, when the dilatation ends at the pylorus; gastro-jejunostomy with jejuno-duodenostomy, or the latter alone, when the duodenum is also distended.

12. Another aspect of this subject is illustrated by Van Zwalenburg's attempt to show by experiment how the mere distention of hollow viscera produces circulatory changes which may predispose to infection and inflammation.

10. West, C. E. *Four Cases of Tuberculous Disease of the Temporal Bone.*

1. The first part of Barr's article takes up the physiology of respiration, with observations he has made on cases of artificial and acquired pneumothorax. He then speaks of the etiology of pleurisy, agreeing with other observers that the vast majority of pleurisies with effusion are tuberculous; dry pleurisies are less apt to be so. He gives in detail his method of treatment by tapping. He recommends complete withdrawal of the effusion in all cases, except in elderly persons with rigid chest walls, and except early in the disease, when there is still febrile reaction. In these cases, before any great negative pressure is established, and before the patient feels any discomfort, he stops the siphon (which he uses in preference to the aspirator), and introduces a quantity of air equal to the amount of fluid which he has withdrawn; he then re-establishes the siphon and completes the withdrawal of the effusion. When all the fluid is withdrawn he injects 4 cc. of adrenalin solution (1-1000) diluted with 8 or 10 cc. of sterile normal saline solution, and if necessary, introduces more sterile air so as to make the total amount equal to a half or three quarters of the bulk of the fluid withdrawn. In cases which he knows to have pulmonary tuberculosis he introduces more air; there is no discomfort. He avoids routine and makes such modifications in treatment as will suit the individual cases. He advises eliminating salt as much as possible from the diet. He then speaks of the work which has been done by other observers and himself on the question of creating an artificial pneumothorax in treating pulmonary tuberculosis, and last he takes up the treatment of empyema.

7. Ryall presents a series of cases of cancer showing the danger of spreading cancer during operations. His cases include cancer of the breast, of the tongue, lip, larynx, etc., cancer of the rectum and cancer of the abdomen. There are numerous illustrations of recurrences which have taken place in stitch holes and along the scar. He believes that cancer infection during operation is responsible for many of the cases of recurrent nodules in the site of operation wound, and that suture-hole infection is exceedingly common. He thinks that this is a danger that cannot be too carefully guarded against, and that any failure to avoid it has an important bearing on the question of cancer recurrence. [J. B. H.]

4. Turton gives the results of seventeen consecutive cases of pulmonary tuberculosis treated with tuberculin. Almost all of these patients have been able or compelled to carry on their usual occupations during the whole or greater part of the treatment. Such measures as could be used at home were advised. In many cases tuberculin was the only treatment. They were cases of all degrees of severity, from the earliest to old standing chronic and advanced cases. He uses new tuberculin with doses of from 1-4000 mgm. to 1-2000 mgm. at intervals of from four to twenty-one days. His only guide as to the time of injection has been the opsonic index, which he has taken frequently, and has endeavored to maintain at a high level: his results are interesting, in the main going to show that cases taken early in the disease will react very favorably to tuberculin without the aid of sanatorium treatment. The chief cause of failure in those cases which did poorly was that the diagnosis was not made early enough, and the second great cause was that for economic reasons the patient could not be removed from very unfavorable surroundings.

He has endeavored to prepare tuberculin from the particular brand of tubercle bacilli found in the individual patient. At present this is too long and expensive a process to be of general use. In many cases pneumococcus vaccine in addition to the tuberculin has been of value, and he believes that injection with the vaccines of the mixed organisms in addition to tuberculin will in the future in many cases bring better results. Whether the results in his cases are better than what could be accomplished by a more vigorous campaign against poor home-surroundings, is doubtful. His results, however, are certainly of interest, and his paper deserves careful study.

[This issue is dedicated to the International Congress of Hygiene and Demography, and all the articles are by men who are leaders in preventive medicine.]

1. Chantemesse describes a method of obtaining an ocular reaction to typhoid toxin somewhat similar to the ophthalmo-tuberculin reaction. To prepare the necessary reagent, typhoid cultures are sterilized at 60° C., the bodies of the bacilli dried *in vacuo*, and triturated for several hours in an agate mortar. The watery extract of the resulting powder is heated to 60° C., and the clear liquid is poured into an excess of absolute alcohol. The resulting precipitate is dried *in vacuo*, and to perform the test 8 to 10 mg. of powder so obtained is dissolved in 1 cm. of water. One drop of this fluid is placed in the lower conjunctival sac of the patient, and it the case is one of typhoid infection a local reaction appears in a few hours, characterized by redness, burning, lacrymation and a small amount of fibrinous exudate. The intensity of the reaction is subject to the individual idiosyncrasies of the patient and to the amount of toxin applied. In persons not suffering from typhoid little or no reaction follows, whereas, if the disease is present, local symptoms are very pronounced, and, what is especially characteristic, persist for one to three days. The author states that in over 200 applications no unpleasant symptoms resulted. In testing 50 non-typhoid patients, no positive results were obtained, whereas, in 70 cases of known typhoid all were positive. In a number of instances the ocular reaction was obtained at an earlier stage of the disease than the agglutination test.

2. Finkler reviews the facts composing our knowledge of immunity, and shows how they all tend to prove varying predispositions to disease in different individuals. The bacteria also show varying degrees of virulence. Predisposition and virulence react upon each other, and must be considered together, never alone, in any discussion of the varying gradations in immunity or in the severity of disease.

3. Pfeiffer's experiments with guinea pigs confirm Flügge's conclusions that inhalation is the main source of tubercular infection, and that the intestinal tract plays only a slight rôle in the etiology of pulmonary troubles.

5. Kossel says that it has been found that not only do persons who have once suffered from typhoid sometimes continue for a very long time to throw off typhoid bacilli in their stools, but even individuals who apparently have never had the disease, but who have been in proximity to a typhoid fever patient, may excrete the organisms in the feces or the urine. This state of affairs may apparently go on for years, so that these individuals for whole decades or even their entire lives may be a source of danger to their environment. The habitat of these organisms in these cases is supposed to be the gall-bladder, which continually reinfects the intestinal contents. Kossel describes in detail several small epidemics of the disease, apparently due to an individual of this sort, who was employed in a dairy supplying milk to the city in which the epidemic in question occurred. This man had worked on the farm for twenty years, and was not aware that he had ever had typhoid fever, yet the bacilli were found repeatedly in his stools. Kossel remarks that in the future it will be necesssary to examine for these bacilli carriers as a further precautionary measure against the contamination of milk.

6. Wassermann reports 102 cases of epidemic cerebro-

spinal meningitis, in which anti-meningococcus serum treatment was used. It had a curative effect when injected early in the disease, and was harmless in all cases. It has no effect after the sub-acute or chronic stages are reached. Doses of 5 to 10 cc. can be repeated two or three times a day. In the severest cases it is injected directly into the spinal canal after withdrawing a little more fluid than is injected. The injections must be kept up after improvement, as relapses are common.

7. Heim says that his former announcement in regard to drying pneumococci on silk threads has not received the attention it deserves. Pneumococci thus dried retain their vitality and virulence for six months at least. The streptococcus mucosus, typhoid bacilli from agar cultures, and diphtheria bacilli dried on threads also retain their vitality a long while. He has kept typhoid and diphtheria bacilli for two years and the tetragenus for five years, with all their properties unimpaired.

2. The author finds a certain substance, which can be split from albumins, which is not chemically definable, and can be separated from the chemically definable products by dialysis. He calls this a "split albumin antigen," or "kenotoxin." Criminals treated with small doses of this toxin developed an antibody specific to it. Mice injected with kenotoxin show marked symptoms, — sleepiness, slowing of the respiration and subnormal temperature. Animals immunized with doses of serum containing the antibody exhibit no symptoms. The same kenotoxin has been found by the author in the breath of animals and man, and also in the fluid taken from an edematous extremity in venous stasis of the part, also in the urine. The author also finds that in certain cases kenotoxin acts as stimulant to the activity of body cells. He claims this is the first time that a specific antibody to a well-marked toxin, not connected with a living organism, has been artificially produced. [*Cf.* Vaughan's work on a toxic substance split off from egg-white.]

6. The benign pemphigus neonatorum, a disease of the fourth to ninth day of life, is, according to Kownatzki, a strictly contagious one, probably due to the staphylococcus, which is usually found in the contents of the bullæ. The disease is spread from one child to another by the nurses, or by some utensil, linen, etc. The author has traced several epidemics from child to child in this manner, and found that after making the nurses wash with special care after handling an infected infant, and sterilizing all linen, bedding, etc., the epidemics came to an end.

7. Abe has examined lice found on typhoid patients. He collected the insects in a sterile tube, immersed them in .1% corrosive solution, then, after rapid and thorough washing, he made an emulsion, with which he inoculated tubes and plates. In each case he was able to demonstrate typhoid bacilli. He concludes that lice may be a factor in the spread of typhoid.

8. Bettmann has, in earlier days, used the older forms of arsenic in the treatment of syphilis. In the ordinary case, he has not seen any evidence that it had an actual effect on the general disease; in gland swellings, in very anemic patients, and on certain types of skin eruption it has worked well. There seems to be an increased tendency to syphilitic angina, to mucous patches, and to moist papules about the genitalia and anus. The author has seen three cases of malignant syphilis, in which mercury was of no avail, clear up under arsenic. Of late he has seen two such cases clear up under atoxyl. There was, however, a return of severe secondary conditions, which did well under mercury. He does not see that atoxyl is any more efficacious than the older forms of arsenic, and points out that it must be used with great care, as it is by no means a non-toxic drug.

6. Vogel, J. *Anuria.*

2. The authors report a series of observations on carcinoma in the mouse. A carcinoma of the mammary gland of a mouse was transplanted successfully, and on examination of the transplanted tumor, a mixed condition was discovered. Among the cancer cells, definite masses of spindle-celled sarcoma had developed. Bits of this tumor, when transplanted to an animal immune to carcinoma, developed into a pure spindle-celled sarcoma, which in turn was successfully transplanted to another animal. Whether this sarcoma existed along with the carcinoma in the first mouse, or whether it was of later development, the authors are not prepared to state.

3. The method used by Diesselhorst for quantitation of mercury in the urine and other excreta depends on electrolysis. He describes his procedure at length. He finds that mercury appears in the urine five days after the beginning of the use of the ointment, and that, after a long course of mercurial treatment, it is present in the urine sometimes for many months. Late in the treatment more mercury is excreted in the feces than in the urine. Slight traces are recognizable in the sweat. After subcutaneous injections of mercury much greater amounts appear in the urine than with enunction, or when mercury is administered by mouth.

5. Observations on the effects which hyperemia of the skin resulting from light treatment had on blood pressure and respiration, led the authors to institute a series of researches on the effect of light baths in angina pectoris. In 26 cases so treated, it was found, after ten baths with a pause of five days between each bath, that a permenent hyperemia of the skin resulted. This means that there is more blood at the surface, less blood in the internal organs, the blood pressure is lowered, and the respirations are easier and deeper. The betterment of symptoms in the 26 cases was marked in many, and evident in all but one. [R. D.]

Revue de Chirurgie. September, 1907.

1. *Terrier, F., and Lecène, P. *The Semilunar Line of Spigelius.*

3. Estor, E. *Congenital Subluxation of the Wrist.* (Concluded.)
4. Pichon, R. *Muscle Herniæ, Particularly Those Due to Simple Rupture of the Aponeurosis.* (Concluded.)

1. The writers point out the historic and anatomic inaccuracy of the term "semilunar line of Spigelius," as applied to the line of origin of lateral ventral herniæ, and recommend its abolition. They consider the true determining factor of the site of such herniæ to be the points of exit of vessels and nerves through the aponeurosis at the outer margin of the recti.

2. Direct trauma to the gall-bladder is of rare occurrence, and generally due to gunshot or stab-wounds. Couteaud reports a personal case and collects others from the literature. The mortality is large and dependent rather on the ensuing peritonitis than on shock, which is relatively slight. [R. M. G.]

The Existence of Vasomotor Nerves in the Brain. O. MÜLLER and SEEBACH (Zeitschr. für Exp. Path. und Ther., Bd. 4, Heft 1, p. 57) report important experimental work which proves that the brain, like other organs, is supplied with a system of vasomotor nerves, which govern its blood supply, independently of general variations in the arterial and venous pressure. The existence of vasomotors in the brain has been denied by the most recent observers, notably by Leonard Hill and Roy and Sherrington. These authors ascribe the increase of volume of the brain noted after cutting the sympathetic in the neck to a passive dilatation of the cerebral vessels, secondary to increased blood pressure. Müller and Seebach show that this is not the case, for the increase in volume takes place before the blood pressure begins to rise. In a long series of experiments they prove in various ways that contraction and dilatation of the cerebral vessels take place independently of changes in the general blood pressure. For instance, after the administration of chloroform, the general arterial pressure falls, while the volume of the brain increases; after small doses of strychnia, on the other hand, the blood pressure rises and the cerebral volume diminishes. Again, after a cold bath, with a rise in the general arterial pressure, there is marked increase in the brain's volume, due to dilatation of the vessels, while the vessels of the face are contracted. The success of the authors is to be ascribed to the excellent methods employed, which included the use of a very delicate plethysmograph to measure the changes in volume of the brain, the measurement of the rate of venous outflow of a cerebral vein at the place where it comes out from the skull, and separate weighing of the head. This last method was devised by Müller, and shows with great delicacy changes in the weight of the head, due to alterations in the blood pressure. Numerous excellent tracings illustrate the work. [W. T.]

COURMONT, M.P. (*La Semaine Médicale*, Oct. 23, 1907), in 57 cases of suspected tuberculous joint disease has obtained positive results in 80% by means of a sero-diagnostic reaction on a principle similar to that of the Widal reaction for typhoid. A few drops of serous fluid aspirated from the suspected joint are added to an emulsion of tubercle bacilli, which are precipitated or thrown into clumps by a positive serum. He has never obtained a positive reaction in joint disease other than tuberculosis.

Correspondence.

LETTER FROM PARIS.

[*From our Special Correspondent.*]

ELECTRIC SLEEP.

PARIS, NOV. 19, 1907.

Mr. Editor: For a long while past I have been trying to bring myself up to the point of writing a letter on the question of electricity in medicine; but each time that I have sat down to meditate on the subject, I have ended in the frame of mind of the man who, when he reached the top of a steep hill, found that his entire load of apples had run out of a hole in the back of his cart. A passerby, seeing him sitting mutely by the wayside, inquired why he didn't say something. To which he replied: "Stranger, I feel I can't do the subject justice."

I have little knowledge as to the status of the electric fraternity at home, so of them I do not propose to speak. In England this branch is evidently in its infancy, the Englishman being apparently less vulnerable to quackery than other people. A German writer recently remarked, in plaintive tones, that the reason why all electric treatments are so fashionable in France and give results there which cannot be obtained elsewhere, is that the French are more "suggestionable." But the truth is that here the very term "electric specialist" stinks to heaven.

Far be it from me to condemn the entire corporation; that would be absurd on the face of it. For in this dough of medical degradation there is a solid leaven of honest men. But a large element of these — lightning-jerkers, let us call them—are the most monumental charlatans that one could well find. And of all the charlatans, *I* ever met, the electric gentleman is the cleverest, — A, No. 1, gilt-edged.

For a number of years, now, the position of the medical practitioner here has been steadily growing more difficult. An English writer put the case very neatly, recently, when he bewailed that there was "no longer enough acute disease to go round!" And I hear that in England also the medical barometer is not at *beau-fixe*, either. When I look back some distance, as I unfortunately can, and think what a general practice was here once, and where it stands now (particularly as regards the occurrence of zymotic disorders), the difference is enormous. I can recall a ward I was in as a student at St. Antoine hospital, and another at the Pitié, in which nearly every bed contained an enteric case, certainly three quarters of the beds of a general service; but two weeks ago the health bulletin of the city of Paris (2,500,000 circa) mentioned 33 cases reported to the authorities during the previous week, with no deaths, something unprecedented. This is for enteric only; but matters are very similar as regards the other infections, always excluding tuberculosis, naturally.

The result of this has been that a number of men have been driven to the wall; and many of them have taken up the electric battery in self-defence. And as electric treatments happen to be all the fashion at present, they are working the lead for all it is worth, their zeal being, if anything, surpassed by that of the serene dodos who troop to their offices month after month, and season after season, always impressed by the mysterious cage, the whiff of wind, the spark that comes out of the knee, or the capillary erection; always being promised relief in a voice of authority, and always looking for improvement, which somehow or other doesn't materialize. Some witty Frenchman once said that whenever he had doubts as to the existence of infinity, nothing set him up so completely as the contemplation of *la bêtise humaine;* and nowhere in medicine does our poor human nature show to such lamentable disadvantage as among these victims of chronic disorders, pursuing the *feu-follet* of an electric cure.

However, let us not, while speaking of the black sheep of the profession, forget the white ones; and it is to one of these that I wish to refer to-day, Professor Leduc, of Nantes.

Leduc is a man who has recently come into considerable prominence. He has, as I understand it, been able to create artificially something that looks like cellular formation, and that appears to reproduce itself. This claim of his has given rise to much controversial argument. More important has been his work on ion-therapy, the introduction of chemical substances into the tissues of the body by means of electricity; and in this department he is said to have accomplished some remarkable results. But unquestionably his most striking achievement has been his demonstration that animals can be put to sleep by means of electricity, and can be maintained by it in a condition such that any operation can be performed on them that could be done on human beings under the influence of ether or chloroform.

I shall not attempt to describe the electric part of this subject, not being competent to do so in any way; the whole apparatus and method has been published in the fullest detail, and any person specially interested in the question can easily obtain Leduc's paper.[1] But I will pass on at once to the portion that interests the general medical reader.

Leduc takes a rabbit or dog, and applies one electrode to the head and the other to the small of the back, using his special and complicated apparatus, and preparing the

[1] Presse Médicale, Feb. 27, 1907.

animal with great care. He then gradually raises the "potential," somewhat quickly at first, afterwards more and more gradually, keeping a close watch on the animal. Any agent that can do away with the functions of the brain (chloroform, alcohol, opium) first stimulates them; and electricity is not an exception to the rule. But although the period of excitement cannot be avoided, it is possible to extend it over as great a space of time as is desired, by means of the deliberation with which the current's potential, and intensity are raised; now the greater the time taken, the less the degree of stimulation and of its ensuing agitation. The latter stage comes just before inhibition and sleep; this is why it is necessary to proceed more and more slowly as the experiment advances.

By following this method the animal is seen to pass into a state of unconsciousness similar to the sleep of chloroform, peacefully, progressively, without a cry, without a movement of defence or flight, and without a sign of suffering! Excepting the fact that reflex action continues, the animal appears to be absolutely insensible, and any operation indicated can be performed, just as on a patient completely under the influence of chloroform.

When it is desired to bring the experiment to a close, the current is shut off brusquely. The animal then comes to at once, gets on its feet, looks quietly about without sign of fear, fright or fatigue, and, as soon as freed from the electrodes, begins to play and eat as though nothing had happened.

There are no sequelæ, no vomiting, rarely any stupor; the experiment seems to cause no suffering, for not only do the animals manifest no sign of pain, but they remain affectionate, show no resentment against the operators, and no fear or revolt during preparations for further applications, which is remarkable in the dog, who is so unerring in distinguishing between those who are good to him and those who are not.

If, now, during electric sleep, the difference of potential in the circuit is steadily increased still further, a moment comes when the respiration stops, and finally the heart does so also. Leduc pauses to remark how different his method is, how infinitely more humane, than the process employed in America for electrocution. With his method the subject feels nothing, and it is not a metaphor to say that he falls quietly into an everlasting sleep. In America, on the contrary, pain and violent contractions occur before perception is abolished; the tension and potential employed are far too great; there is violent reaction and a setting free of heat, which burns the subject and makes it necessary to interrupt the current at the end of a few seconds only; the victims then sometimes revive, and several successive applications have to be made to produce death. With the intermittent current, applied according to Leduc's method, no more than the very slight intensity necessary to stop the heart is used, and the application can be prolonged so long as desired, without any interruption.

The tolerance of animals for electric sleep is something remarkable; one rabbit was kept under experimentation for four hours fifty minutes, and another for eight hours twenty minutes, without unfortunate consequences. The same animal can be put to sleep a great many times without any ill effects to health.

However, we have still the climax of this affair to relate. Leduc has the courage of his opinions, and not being satisfied with experimentation on animals, looked about for more important material. I imagine that applicants for the experiment were not easy to find, so he was reduced to trying his system *on himself!* That is, he persuaded two of his colleagues of the Nantes Faculty of Medicine to put him to sleep with his apparatus; and it is perhaps difficult to say which of the participants required the greater nerve,— the subject or the operators. This is how he describes the experiment:

"The feeling produced by the stimulation of the superficial nerves is easily borne, though disagreeable; it soon lessens, as in the case with the continued current, and after passing a maximum, decreases in spite of the increase in power. The countenance is red, there are slight contractions of the muscles of the face, neck and forearm, and fibrillary tremulations are observed, followed by tingling of hands and finger-tips. This tingling then occurs in feet and toes. Inhibition first affects the centers of speech, the motor centers are entirely inhibited next, and then the subject is unable to react in face of the most painful stimulation and can no longer communicate with the experimentors. The limbs, although not in complete resolution, show no stiffness. A few mutterings are heard, not caused by any pain, but due apparently to stimulation of the muscles of the larynx. In these experiments the pulse remained altogether unchanged; but breathing seemed a little labored.

"When the maximum current was reached I still heard what was said about me, though as in a dream; I was conscious that I was unable to move or speak to my colleagues; I felt contact, pinching or pricking, but the sensation was dull, as though in a limb deeply numbed. The most disagreeable impression was that of following the dissociation and successive disappearance of the faculties; this feeling is the same as that of a nightmare during which, in presence of some fearful danger, you can neither cry out nor move. Still, I was always sufficiently conscious to be able to regret that my colleagues did not raise the current enough to produce complete inhibition. After this first experiment we began again (! !), intending to go still farther; but this time my colleagues, thinking that inhibition was complete, once more halted before entire abolition of consciousness and suppression of sensation. In these two consecutive experiments I remained twenty minutes under the influence of the electricity. When the current was shut off, I awoke at once; I felt no after-effect whatever, unless it were a feeling of well-being and physical vigor; and immediately subsequently I went and delivered a speech before a society for labor-pensions, of which I am an honorary member."

In reply to a note, M. Leduc has been good enough to write me that this is the only experiment of the kind on record, so far as he knows, and I can well believe him. Perhaps, were a state of tension of such gravity to arise between myself and the powers-that-be that my presence on this globe was felt to be no longer tolerable, I might call on Leduc to lend me his services as an obliging *confrère;* but otherwise I feel that nothing on earth would induce me to have such an experiment tried on me. I always bear in mind the words of wisdom inscribed over the door of a mill in the West: "Visitors are requested, in their own interest, not to monkey with the buzz-saw." There is nothing so ticklish, or so ready to go wrong, as complicated electric apparatus. Some hitch, and a few extra volts through your head would send you to the grave, and the operator to the gallows; and I should hate to do that.

"Spectator."

NOTES ON X-LIGHT. NOTE 203. ON THE USE OF FUSED SILICA IN VACUUM TUBES.

Boston, Thanksgiving Day, 1907.

Mr. Editor: In Note 84, an inexpensive method of making x-light tubes was described and illustrated. As the price of x-light tubes has steadily advanced until now durable tubes cost about fifty dollars, it is desirable to call attention to the method mentioned. Instead of the bulb being blown it was molded in a glasshouse, with end tubes of sufficient diameter to admit the terminals without expansion. All that was necessary to complete the tube was to seal in the terminals and exhaust. The stems of the terminals were supported by disks of mica or lava at first, afterward of glass. Now that fused silica can be obtained, it is recommended for these disks, as it does not crack and gives off little gas. In several later notes the use of radio-active substances in vacuum tubes was recommended for regenerating the tube and for ionizing the gases to make them better conductors. The radio-active materials were used in small glass tubes sealed within the vacuum tubes, a current of electricity being sent through the radio-active material when more gas was desired. As these glass tubes were liable to crack when being sealed in and afterward in use, the employment of quartz tubes, both for the radio-active regenerator and automatic vacuum regulator is here recommended.

Very truly yours,

William Rollins.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING NOV. 30, 1907.

G. C. THOMAS, acting assistant surgeon. Appointed acting assistant surgeon from Nov. 20, 1907.

W. H. BUCHER, surgeon. Detached from the Naval Hospital, Boston, Mass., and ordered to report to the surgeon-general, Navy Department, for special temporary duty, and thence to the Naval Hospital, New Fort Lyon, Colo.

U. R. WEBB, passed assistant surgeon. Ordered to command the Naval Hospital, San Juan, P. R.

H. C. TAYLOR, passed assistant surgeon. Detached from duty at the Naval Hospital, New York, N. Y., and ordered to the Naval Hospital, New Fort Lyon, Colo.

SOCIETY NOTICE.

THE NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — This Society will meet Thursday, Dec. 12, 7.30 P. M., at Hotel Nottingham. Section of Surgical Gynecology, Dr. Sarah E. Palmer, *Chairman*. Papers: Reports of two cases of Tuberculosis of Kidney and Bladder. Dr. Clara J. Alexander. Report of a case of loculate bladder with proteus infection. Dr. Sarah E. Palmer.

BLANCHE A. DENIG, *Secretary*.

RECENT DEATHS.

DR. THOMAS WILDES, of New York, died on Nov. 28, from cerebral apoplexy. He was sixty-eight years of age and had been for some time in the service of the City Health Department.

DR. JOHN ADAM SCHMITT, of New York, died suddenly on Nov. 26, in the fifty-sixth year of his age. He was graduated from the University of Giessan, Germany, in 1875, and was gynecologist to the Yorkville Hospital.

DR. WILLIAM G. RUSSELL, of Brooklyn, New York, died on Nov. 27. He was a native of New York City, and was graduated from the Long Island College Hospital in 1871. He had practiced in Brooklyn for over thirty years, and at the time of his death was consulting physician to the Williamsburgh Hospital.

DR. WALTER JOHN NORFOLK, a retired physician, died at his home in Plainfield, N. J., on Nov. 25, at the age of fifty-nine years. He was born in Salem, Mass., and was a graduate of the Harvard Medical School.

DR. JOHN M. JULIEN, of Pleasant Valley, Dutchess County, N. Y., died suddenly on Nov. 24, from pulmonary hemorrhage. He was of French descent, his grandfather, John Marius Julien, having served under Napoleon Bonaparte in all his principal campaigns, and he himself was an orderly in the French army during the Franco-Prussian War. He was graduated from the Long Island College Hospital, Brooklyn, in 1880.

VERRUCÆ PLANTARES; THEIR PREVALENCE IN BOYS AND IN YOUNG MEN, AND THEIR PATHOLOGY.*

BY JOHN T. BOWEN, M.D., BOSTON,
Edward Wigglesworth Professor of Dermatology, Harvard University.

THE first to call attention to these plantar warts was W. Dubreuilh.[1] Up to that time the affection had not been referred to in the treatises on surgery or dermatology, although, as he states, it is far from uncommon. His description is so good that it may very properly be quoted:

"When the plantar wart is of recent date, it shows itself in the form of a slightly reddened elevation covered with a thin epidermis. When this covering is removed, bleeding appears from a number of orifices.

"Most often, however, the lesion presents at first sight the aspect of a large and extremely tender callus. The horny layer is thickened and elevated; sometimes the central part of this horny plaque is perforated by a sort of well, more or less deep, especially if there has been an attempt to scrape it off. If, however, the lesion has not been molested for some time, the superficial horny layer forms a complete covering.

"When the surface of the lesion is cut with a knife, the periphery of the lesion is found to have a hard, semi-transparent, horny layer, much like normal horny epidermis, or that which constitutes calluses and corns. Instead, however, of penetrating deeply into the corium with a horny mass as does the corn, this lesion possesses a soft and depressible central portion. It takes the form of a ring perforated by an orifice which becomes larger as one goes more deeply. This central part possesses a tissue of a very different appearance, a horny tissue, to be sure, but white, opaque and milky; it is soft and resistant to the knife like wet tow.

"While the horny ring at the periphery is homogeneous or stratified, the central part appears to be fasciculated and formed of columns which penetrate vertically downwards. Frequently a dark, hemorrhagic point is seen, and most often, if one continues to cut successive layers of the lesion, drops of blood are poured out from a large number of capillary openings which dot the surface.

"It is at first difficult to make a curette penetrate into this soft and tenacious tissue. When once, however, the curette has reached its base, a soft, white, milky tissue is removed, which is divided into columns that run perpendicularly from the surface to the base."

Such is Dubreuilh's description of this affection upon the soles of the feet. With regard to its frequency, I have been much impressed by the large number of cases seen and heard of in and about Boston. Almost all of the cases are in young people, and the affection is especially prevalent in preparatory schools and colleges. Dr. Bailey, the medical visitor of Harvard University, writes me that he sees a large number of these cases every year, and that they average about twenty operations a year for plantar warts at the Stillman Infirmary, the hospital of the University. A great many cases occur, also, in the preparatory schools at Groton and Southborough. I have been unable to collect exact statistics on this point, as they were treated by different people, and sometimes I heard of cases which had not been treated; as, for instance, a boy who was my patient told me that perhaps half a dozen other boys of his acquaintance had similar lesions.

I have been able, however, to study thirty-four cases, which I have seen and treated in my private practice, and of which I have preserved notes. In hospital practice the affection is far less common. We see it so rarely, that statistics from this source would be of little value. Of these 34 cases, 28 were males and 6 were females. The youngest was ten and the oldest sixty. Seven were under sixteen, 15 were between sixteen and twenty, 7 between twenty and twenty-five, and 5 between twenty-five and sixty. It is seen, therefore, that youths and boys under twenty years of age are the ones by far most frequently affected.

Twenty of these 34 cases were in boys who were attending either a preparatory boarding school or Harvard College. In almost all instances the boys would speak of some other boy or boys of their acquaintance who had the same affection, so that the conclusion is justified that in this vicinity, at least, the affection is far more common among boys and youths who are collected in schools and colleges than among other people. Its prevalence in this class is further corroborated by the local physicans in the neighborhood of these institutions.

Dubreuilh considers that local traumatism plays an important part in the development of these lesions. In the cases that I have studied, it was impossible to decide that in any of the cases there had been a local injury. He also thinks that the localization of these lesions is in favor of the traumatic theory, in that they are especially common over the head of the third metatarsal bone. In my cases this localization was not so apparent, although it did occur in a number of instances. Contrary to Dubreuilh's experience, I have seen a number of times the coincidence of plantar warts with a like affection of the palms of the hands, and I have had two cases where they appeared on the palms alone. In one or two cases there had been a palmar wart preceding the attack of plantar warts.

As to the number of these warts, they may be few or many. In one of my cases there were as many as thirty. In two of my cases two members of the same family were affected either at the same time or at a short interval from one another. In one case it was two brothers aged respectively fifteen and twenty-one, and in the other, two sisters of whom the oldest was twenty. It must be admitted that the evidence here stated does not warrant the conclusion that these lesions are contagious, and yet there is enough to make

* Read by title at the Sixth International Dermatological Congress, New York, September 1907.

[1] Ann. de Derm. et Syph., Tome 6, 1895.

such a theory probable. It is quite true that people most subject to these plantar warts are those who are most accustomed to exercise, such as running and tennis playing, and that in these sports an opportunity for irritation of the plantar surfaces is plainly offered. On the other hand, this traumatism can be invoked as offering an opportunity for infection in such cases, and the well-known contagiousness of verrucæ vulgares would be a point in support of this theory.

CASE I. Boy of eighteen. Verruca of the sole of the foot, just below the third metatarsal.

CASE II. Boy of sixteen, who lived at home and attended a day school. He had a verruca of the sole of the foot, which had lasted several months. He said that two years previously he had had a similar lesion on the palm.

CASE III. A boy of fourteen, at a day school. Lesion is situated upon the heel.

CASE IV. A lad of eighteen, who presented three large lesions on each sole, opposite the end of the third metatarsals.

CASE V. Girl of sixteen, who presented a lesion on the ball of the foot.

CASE VI. A youth of nineteen, in college, who presented several lesions on the soles of each foot, the exact number not stated in the record.

CASE VII. A man of twenty-six, one large extensive lesion of the flexor aspect of the thumb.

CASE VIII. Boy of ten, a lesion on the sole of each foot over the metatarsal ending, of six months' duration.

CASE IX. A youth of twenty, who had had multiple verrucæ of the soles of the feet for six months.

CASE X. Youth of eighteen, who had two verrucæ of the soles, besides a large callus.

CASE XI. Young man of twenty-one, who had several lesions at the base of the toes.

CASE XII. Girl of fifteen, with a lesion of the palm of the hand.

CASE XIII. Boy of fourteen, at a boarding school, a verruca of the sole.

CASE XIV. Youth of twenty, a verruca of the heel.

CASE XV. Young man of twenty-one, in college, who had had verrucæ of the ball of the foot for two years, beginning while he was at boarding school, while he was exercising in the fives court. He also had had one of the palm of the hand, which had disappeared.

CASE XVI. Boy under sixteen, at boarding school, who presented verrucæ of the heel.

CASE XVII. Young man of twenty-one, at college, who presented six or eight lesions of the ball of the left foot, which first appeared two years ago, when he was not exercising very much.

CASE XVIII. Young man of nineteen, at college, a verruca of the sole, which had lasted for six or eight months.

CASE XIX. This was a boy of fifteen, at boarding school, a brother of case No. XV, who had a wart of the palm of the hand of three months' duration. This lesion had once been excised by a local physican and had recurred in the cicatrix.

CASE XX. Young man of twenty-one, who had had verrucæ of the sole of the foot for a month.

CASE XXI. Young woman of twenty, who had had, for nearly a year, a plantar wart on the left foot over the third metatarsal. This appeared at the time that she was visited by her sister, who had a similar one. She slept in the same room with this sister, but not in the same bed. Both played tennis, but, so far as could be remembered, had never worn each other's shoes.

CASE XXII. A man of fifty-three, a merchant, who presented a plantar wart over the first metatarsal bone.

CASE XXIII. A young man of twenty-two, in Cambridge, an oarsman, who rowed in the University boat, presented quite extensive lesions of the palms, and also of the sides and backs of the hands. Those of the palms were typical palmar warts. Those of the backs of the hands presented the aspect of ordinary seed warts. There may have been twenty of these lesions altogether. The affection had lasted for three years.

CASE XXIV. Young man of sixteen, living at home, who showed eight or ten plantar warts, chiefly over the metatarsal bones.

CASE XXV. A young man, over twenty. A palmar wart of identical histological appearance with the plantar wart. Also a wart under the nail.

CASE XXVI. Man of fifty, who had had a plantar wart on the sole of the right foot for nine months. It had appeared immediately after a trip to Mexico.

CASE XXVII. Woman of sixty, who presented a half-dozen plantar warts over the metatarsal region.

CASE XXVIII. Young man of twenty-one, who had had a verruca of the sole of the foot, in the metatarsal region, for six months.

CASE XXIX. Young woman of eighteen, who had a palmar wart on the middle finger of the right hand.

CASE XXX. Boy of sixteen, at boarding-school. This was the most extensive case I have seen. Thirty plantar warts, scattered over the whole surface of the sole of the left foot, were counted at one time. There were also some on the plantar surface of the toes. They had first made their appearance six months before. Besides these there were two typical lesions of the palms, which had appeared after those on the soles.

CASE XXXI. Woman of thirty, who had a palmar wart, associated with the ordinary verruca vulgaris of the back of the finger.

CASE XXXII. Boy of fourteen, at boarding school, who had had for six months several plantar warts in a clump on the plantar side of the great toe.

CASE XXXIII. Young man of twenty-one, who had four or five plantar warts in the metatarsal region, of eight months' duration.

CASE XXXIV. Boy of fourteen, at boarding school, plantar wart of the heel.

Melchior-Robert, in the *Annales de Derm. et de Syph.*, 1897, describes four cases, two palmar and two plantar, but without histological examination. He gives the name *verrue en puits* to that form that projects from the surface, but in which the papillary prolongations are deeply seated, and this is the type of both the plantar and palmar warts that I have examined.

D. W. Montgomery read a paper at the fifty-fourth annual session of the American Medical Association on "Papilloma of the Sole," in which he relates 7 cases which he has seen and treated. Four of these were in people under twenty. He refers to the well-like aperture that is uncovered when the outer horny layer is wanting or is removed by cutting.

At the meeting of the Dermatological Society of Great Britain and Ireland, on March 25, 1896,[2] Dr. Eddowes read a paper entitled "Warts on the Feet." Having previously been interested in this subject, he agrees entirely with Dubreuilh as to the clinical appearances of these growths, but had made no microscopical examinations.

[2] Brit. Jour. of Derm., May, 1896.

He considers that traumatism plays a prominent part in the production of these lesions.

The pathology of these lesions has been very thoroughly worked out by Dubreuilh, and with almost everything he says I can concur. I have examined microscopically more than twenty different cases of plantar and palmar warts, and in some instances several lesions from the same case were studied. In connection with these investigations a number of specimens of verrucæ of different histological appearance were also examined.

In the following description of the histological appearances I am, to a great extent, in accord with the very excellent description of Dubreuilh. In verrucous growths, which are not subject to habitual pressure, as on the back of the hand, the tumor is developed as a projection above the surface of the skin. In places, however, where there is a long continued and strong pressure, the wart does not project to any extent, but burrows, as it were, into the cutis, while the adjacent epidermis becomes hypertrophied. A section through the center of one of these palmar or plantar warts explains the characteristics obtained by curetting, for the wart is, as it were, subcutaneous and the similarity to a well is very striking.

There are no important changes in the cutis. The papillæ contain a certain number of cellular elements. I have not found the elastic fibres in the upper portion of the papillæ wanting as has Dubreuilh. In most of the lesions that I have examined, the papillary projections and interpapillary prolongations were much flattened out at the center, whereas I have in all cases noticed the lengthening out of these structures at the periphery of the lesion. In some instances they run almost horizontally to the surface at the periphery.

As regards the epidermis, an interesting feature, peculiar in my experience to these plantar and palmar warts, has been described by Dubreuilh. I have found it constantly in verrucæ of the palm and sole, never in other situations, while Dubreuilh describes it as occurring in a wart on the back of the hand. This change gives rise, in the center of a large and well-developed palmar or plantar wart, to a most extraordinary peculiarity.

Serial sections through an entire lesion show at the periphery the appearances in general of an ordinary verruca, a pronounced acanthosis, papillary enlargement, and down growth of the rete plugs, together with a very pronounced hyperkeratosis. The granular layer is much increased in thickness. Very soon, advancing toward the center of the lesion, the peculiar change described by Dubreuilh is encountered. This consists in a vacuolation of some of the rete cells, which causes them to assume a rounded form and a larger size than the neighboring cells. The lower basal cells I have never seen thus affected, but the appearances may often be seen in the layers near the basal cells. Oftentimes small clumps of rete cells are thus affected while the cells above them still retain their normal characteristics. Usually, in connection with this vacuolation, there is a precocious development of keratohyaline, which often is heaped up at the periphery of the cell around the central cavity. These cells retain their nucleus, which, as a rule, is very much swollen. Advancing toward the center of the lesion, this vacuolation affects more and more cells, which fuse together until at the center of a well-developed lesion, the portion corresponding to the rete is composed of a reticulated tissue heaped up with masses and blocks of kerato-hyaline.

The largest portion of the lesion is composed of the horny layer, which lies, much hypertrophied, over the reticulated rete as just described. That this layer is imperfectly keratinized is shown by the presence in places of the cellular elements, which take the stain of the ordinary reagents.

In one of the first of these lesions that I examined, peculiar bodies were found in many of the nuclei of the rete cells. The appearances at first sight were so striking that the suspicion that they might be some form of protozoa was aroused, and it was on this account that I examined, histologically, so many cases. These bodies were found in a majority of all the cases, not, however, in all. They are small, usually round bodies, highly refracting, occasionally appearing as if concave in the center, and, in a few instances, crescent shaped. As a rule, they are all of equal size. They are first seen in the third or fourth row of rete cells and seem to go hand in hand with the vacuolation, as they disappear when what corresponds to the granular layer is reached. They are not seen in all the nuclei, but are most prominent in the enlarged and swollen nuclei, which accompany the vacuolation. They are stained by the acid reagents, and are sharply differentiated in this way from the rest of the nucleus. No further data as to the significance and origin of these nuclear bodies could be obtained, and, so far as I know, such appearances have never been described in epithelial structures. It was, as I say, natural at first to think of the possibility of their being some form of protozoa, and it is difficult to rule out such a possibility. On the other hand, their appearance in connection with the vacuolation, and their disappearance in the upper layers, would make it more probable that they represent some form of nuclear degeneration or alteration.

TREATMENT.

I have had experience with quite a number of different modes of treatment in this affection. In many instances it was not possible, on account of the prejudice of the patients or their parents, to institute as radical methods of treatment as seemed advisable. In a considerable number of cases salicylic acid in collodion in 10% strength was sufficient, after some time, to remove the lesions. It was painted on daily, and the foot soaked every other day for twenty minutes in hot

water, and then pumice soap used to remove as much of the lesion as possible, and then the painting renewed; much the same treatment that is used in the case of corns.

Many cases, however, will not respond to this treatment, and I have had some success with chrysarobin, which was added, in 10% strength, to the salicylated collodion. In other cases success was attained by covering the lesions constantly with a 60% salicylated gutta percha plaster. It is my impression that almost all of these lesions will yield to this treatment, if it is persisted in long enough, but it may take many weeks, and the necessary patience has not been found in all persons.

Dubreuilh considers curetting the most radical and rapid treatment, which he performs under cocaine anesthesia. The late Dr. Warren, of Groton, who had treated a large number of these cases in the boys of Groton School, wrote to me that he had formerly excised these lesions, but had given it up; that he had tried salicylic acid, corrosive sublimate, chromic acid, nitric and lactic acids; he had also used electrolysis, but had come to the conclusion that the Paquelin cautery was the best, surest and quickest method. He first cocainized the wart, and with the round point of the Paquelin cautery thoroughly cauterized, beginning at the center and sweeping round the whole periphery of the wart. This method he considered almost painless, produced the smallest possible scar, and needed but one sitting, if carefully done. With regard to excision, it has to be thoroughly done, and is practiced with success at the Stillman Infirmary in Cambridge, where, as I have said, they average twenty operations a year for this affection. Even, however, when apparently thoroughly done, the lesion may reappear in the cicatrix, as I have myself seen.

Electrolysis has been effective in my hands, but without thorough local anesthesia it is very painful, and the same may be said of the strong caustics, which I have repeatedly tried. By the advice of other practitioners, a number of the patients whom I have seen have been wearing plates in order to remove the weight from the part affected by the wart. I have rarely seen a cure produced by this mode of treatment alone.

THE CORRECTION OF MALOCCLUSION AND ITS RELATION TO RHINOLOGY.*

BY ALFRED P. ROGERS, D.D.S., BOSTON.

IN undertaking this study of malocclusion it will not be my purpose to carry you through a mass of detail; but to present to you as clearly and briefly as possible the fundamental principles of the practice of orthodontia, laying special stress upon those ideas which we believe are of vital interest and practical value to the rhinologist. That malocclusion of the teeth is sometimes directly responsible for the maldevelopment of the facial bones, and that various pathological conditions of the nasal or post-nasal space are responsible for retarded development of the facial bones, and malocclusion of the teeth, needs scarcely any emphasis. It is undoubtedly true that there are numerous features attending these conditions, which we must work out together in order that we may become more efficient in our practice, and more valuable to those it is our privilege to serve. It is with this idea in mind that I present to you this study, hoping it may in a measure assist in a clearer understanding of the work being undertaken by the orthodontist, and of pointing out its practical value to the rhinologist when he is considering those cases where lack of development hampers him in the attainment of the greater good. While for many years the correction of irregular teeth was regarded for its esthetic value alone, later development in the field of orthodontia has established the fact, that the correction of malocclusion is far-reaching in its beneficent results; that although the esthetic value cannot be overestimated, the other features are of such immense value and importance as to create a new profession, composed of men whose consciences have been so awakened to the immense necessity for their work, that they are compelled to devote their entire time and energy to its accomplishment.

It has long been observed that certain facial and dental inharmonies accompanied nasal stenosis, and are great in proportion to the degree and duration of the nasal obstruction. It is in this particular field that the orthodontist seems to be of greatest value to the rhinologist, because it is his mission to stimulate growth, to restore harmony between the distorted dental arches, to influence the development to such a degree that nasal respiration is more easily accomplished, as well as to change inharmonious facial lines to those of grace and beauty.

We have all seen and known too much of the struggles of childhood, due to faulty respiration, to depreciate even the humblest efforts at its correction; or the endeavor to dispel the harmful and far-reaching results in development which are known to affect not only the face and nasal cavity but the mouth, the pharynx, the thoracic walls and, indeed, the entire system. Although oral respiration is usually confined to childhood, its effects are known to have a greater or less disastrous effect throughout life. The greatest period of suffering is experienced during those years of child life when the facial bones are developing and the teeth are in the process of erupting. The dental arches and the contiguous bony structure seem to be the greatest sufferers. The upper arch and the bones of the middle face are most frequently referred to, by writers on rhinology, as being those which suffer almost exclusively. The lower arch is frequently referred to as being normal in its development; but a close study of malocclusion shows that the lower arch is very frequently malformed; indeed, in very many cases it takes a position distal or mesial to the normal, thus aiding in destroying the facial lines, the type, and even changing the

* Read before the New England Otological and Laryngological Society, March, 1907.

individuality of the subject. The bones of the face are so closely allied that the stimulation of one part readily acts upon another. Therefore, it will be seen that in order to claim the desired advantage, the treatment of these cases must be undertaken very early in life. The removal of spurs, of inferior turbinates, of adenoid growth, seems but a partial remedy. What is mostly needed in these cases is the vigorous co-operation of rhinologist and orthodontist, with a view to a clearer and better understanding of each other's work, and a determined effort to accomplish the desired treatment *before the active period of growth is passed.*

In order to gain an intelligent idea of the correction of malocclusion and its influence upon development, it is necessary for us first to have a clear and definite understanding of occlusion. This picture shows us very beautifully the normal occlusion. (Fig. 1.) It is the basis of all opera-

tions in orthodontia. It is the goal toward which every conscientious operator must direct his efforts. If we examine carefully we shall see that perfect occlusion is incompatible with any degree of irregularity, but that all the teeth with their grooves and inclined planes must be in the greatest harmony, and when this is present, harmony exists not only between the teeth themselves but between the arches, the facial bones, and the overlying muscles. A thoughtful study of this picture cannot fail to convince one of the wonderful influence of these numerous inclined planes in the part they play in influencing, not only the erupting teeth in taking positions of occlusion or malocclusion, but also the arches and facial bones themselves; because a misadjustment of these inclines rarely if ever fails to produce marked malocclusion, whose evil influence does not confine itself to the teeth alone, but to the adjacent tissues as well. Another valuable suggestion which may be received from the study of these inclines is, that these cases are never self-correcting, as many are led to suppose; but must continually grow more desperate and carry the evil effects to a greater and deeper extent. It might be well to emphasize at this point the influence of these inclined planes upon the developing bones. Very serious and far-reaching effects are noticed upon the mandible, where the process of growth may be most seriously handicapped by the adverse influence of these inclines. It is well known to you that the development of this bone in the molar and bicuspid region is from behind forward by a wedging process, when the growth is most active during the eruption of the teeth. If for any reason the inclined planes of the lower molar occlude distal to the normal position, the growth is interfered with. This is exactly what occurs in many cases with the history of continued nasal obstruction, and it is a point well to be considered by the rhinologist and orthodontist. It is well also to bear in mind that the lower arch is of great importance at this period of development, because it is the mould over which the upper arch is swedged. If it takes a position distal to the normal the arch is so shortened that the upper arch must cease to grow, while nature strives to establish as efficient an occlusion as possible. With this endeavor, the growth of the facial bones becomes greatly interfered with, the arches become distorted and narrow and the eruption of certain teeth delayed or entirely prohibited. When this retarded development takes place with the upper central incisors, deflection of the nasal septum may follow. This fact has recently been brought to our attention by Dr. H. P. Mosher, whom I believe has established the fact that a large percentage of tardy eruption of the central incisors has a direct influence upon the nasal septum. We can easily see then how a single misdirected force together with oral respiration may result in the most alarming type of malocclusion which, if left past the age of fourteen or fifteen, will be serious and difficult in treatment, but at the early age of six to twelve, could have been treated with ease, the beneficent influence of the inclined planes reserved, and the development of the facial bones carried on with but little interruption. Before passing on, I wish to point out for diagnostic purposes the relative postion of the first molars. In classifying malocclusion, these points have been found the most reliable for the purpose, as they denote conclusively the mesio-distal relationship of the arches. In the greater number of cases of malocclusion, these molar teeth are in their correct position, but many cases are presented to us in which this condition varies.

In our study of malocclusion and comparison with normal type, we must remember to notice the points of similarity or dissimilarity in the molar regions and between the arches themselves. To make our study more comprehensive, we will imagine that we are examining and comparing with the normal type a few hundred models of malocclusion. Before our search has been long continued, we will not fail to notice that a large number of our models present points of similarity. We will notice that in these cases occlusion of the first molars is exactly as found in normal occlusion. Building upon this point of similarity, we select from our collection all the models bearing this distinction and we have established the great first class of malocclusion. (Fig. 2.) Having satisfied our minds upon the first great class, further search will reveal to us a number of models that differ in a marked degree from the

standard. This time the lower arch seems to be distal to its normal position. (Fig. 3.) Sometimes this occurs on one side and sometimes on both. Another characteristic shows itself in this classification, namely, the protrusion or retrusion

of the anterior teeth. We, therefore, cannot classify without subdivision or subclasses. We will, therefore, divide this second class into two divisions, each division having a subdivision. In the first division, we will place those models

Fig 3

having protruding upper incisors, where the lower arch appears bilaterally distal. The subdivisions of this first division consists of those where we find protruding upper incisors and where the lower arch is unilaterally distal. The second division of this class will be made up of those models having retruding upper incisors and where the lower arch is bilaterally distal; in the subdivision of this class, we will place those models with retruding upper incisors and unilaterally distal arch. This completes the classification of the second class. The remaining few models will present a very marked characteristic which will readily place them in the third class. (Fig. 5.) This time we will notice that the lower

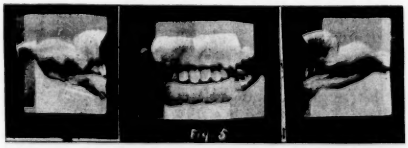

Fig 5

arch is mesial in relation to the upper. Most of these cases are bilaterally distal; these we naturally place in a division by themselves and with the few remaining, we will form the subdivision of the third class. Mouth breathing may be associated with any one of these conditions. Why so many and varied types should result is yet unsolved, but it seems that the period and degree of nasal stenosis must be an important factor.

The diagnosis of impending malocclusion and retarded development of the facial bones may be made at a very early age, sometimes early in the first year. During the first six or seven years of child life ample opportunity for diagnosis of future conditions is given; because it is during these years that those adverse influences are usually at work, and when the bones and teeth are most easily influenced. Nasal obstruction, however, is not the only cause of retarded development. It seems that in order to gain the broadest and most correct ideas we must go further, and look well into the *vital forces of the child.* Dr. Bogue has very clearly emphasized this idea when he says, that "Many of the evils that we, as orthodontists, are called upon to treat, and many of the diseases which confront the rhinologist, arise from a deficiency in the vital force of the child; an inability to overcome some mechanical obstruction. Every developmental process is an expression of vitality. Every defect in conformation or function is an indication of a deficiency in a motor center of power sufficient to overcome obstruction." Another influence which deserves careful consideration is *the lack of use.* If function for any reason is suspended, it is quite true that development is also retarded. Doubtless the average child fails to properly perform the function of mastication, his food is soft and yielding; therefore the lack of proper mechanical stimulation is followed by the inevitable lack of development.

Retarded development is very frequently noticed at the age of six or seven when the arches are so narrow that the eruption of the permanent incisors is seriously interfered with. (Fig. 6.)

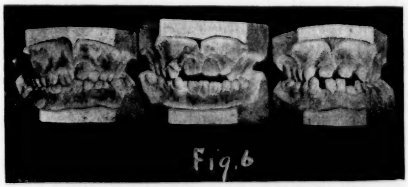

Fig. 6

This condition is directly due to a lack of anterior development, which should have taken place before the loss of the temporary teeth. At this age when normal conditions are present, an enlargement of the anterior segment of both arches takes place. This enlargement is manifest by the

gradual separation of the temporary teeth, when a well-defined space is noticed between each tooth in the anterior segment. (Fig. 7.) When this growth is present and the arches are in correct

mesio-distal relation, normal development may be expected. Should this anterior development be lacking, retarded eruption of the incisors will occur, and, if accompanied by a distal position of the lower arch, the most aggravated form of malocclusion may be expected, with distortion of the dental arches and arrested development of the facial bones and disfigurement of the facial contour. (Figs. 8, 9.) This illustration is that of a

boy six years of age. In spite of the fact that his adenoids were removed very shortly after their discovery, and at the age of two and one-half years, the lack of development in the arches with the distal position of the lower arch forms a well defined case of class two, with the usual serious defects upon the developments of the facial bones, as shown by a study of the facial contour. The study of the profile shows a

decided lack of growth in the mandible. Allowed to progress without skillful orthodontic treatment, this would develop into a case similar to that illustrated in Fig. 3.

My desire is to point out that all these unhappy conditions may either be prevented or corrected, and the child allowed to develop and attain its normal type. When lack of anterior growth is evident, that section of the arch should be gently stimulated by painless and gradual methods until the exact space for the permanent incisors is developed. They will then appear unhampered during the period of their eruption, and the deflected nasal septum from this cause will be less in evidence. Should the mesio-distal relation be incorrect, the arches should be placed in their proper relation before the eruption of the first permanent molars in order that the inclined planes of these teeth may properly engage themselves and normal development continue.

Fig. 10 shows us very clearly what may be accomplished in widening the arch. The small model is that of a boy of twelve who had suffered from nasal obstruction during the period when active development should have taken place. The evil results are clearly shown in this narrow, constricted arch. It will be noticed that development is so retarded that there is absolutely no room for the eruption of the cuspid teeth. The larger model represents the corrected case and shows what may be accomplished by proper

stimulation and careful expansion of the dental arch. Careful measurements show that at a point on the vault directly above the first bicuspid teeth and one-half inch above the gingival border, the vault of the untreated model measured exactly twenty-five hundredths of an inch, whereas the measurement taken from the same locality upon the completed model shows a development of seventy hundredths of an inch. These measurements are important, in that they show that the apices of the teeth have been moved very extensively and widening of the entire arch has occurred. In this particular case there seems little doubt but that the floor of the nose has been considerably widened. My belief is based upon the fact that the patient has experienced a wonderful improvement in his ability to breathe correctly. This improvement has been gradual, and I believe will continue until the bony development which shall follow the widening of the arch has become complete. Dr. Pullen, of Buffalo, and Dr. Reoch of Boston, have noted similar improvement in nasal respiration following the excessive widening of the upper arch.

Fig. 11 illustrates a developing case of the

second division of class two in the temporary denture. There is present a lack of anterior development (or interstitial growth). There is also present a distal position of the lower arch. The upper first permanent molars have just erupted. The lowers are about to erupt. With the arches in this condition, we will have adverse action of the inclined planes of these molars when they come in contact, thus further retarding the growth of the mandible. Development of the anterior segments and a slight mesial movement of the mandible to allow the proper occlu-

sion of the first molars is the simple treatment required here; but if not accomplished the case will result in severe malocclusion.

Fig. 12 shown simply to illustrate a case of the second class treated for a young woman of nineteen years. The changes here noticed were accomplished in four months without pain or special inconvenience and with very pleasing facial results.

Fig. 13 is shown to illustrate what very satisfactory facial improvment may be accomplished. This is not an unusual result following the correction of malocclusion and the stimulation of the contiguous bony structure.

A CASE OF SUPRAPUBIC CYSTOSTOMY ON A PROSTATIC; WITH REMARKS ON THE TECHNIC AND INDICATIONS OF THIS OPERATION.

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

PROSTATIC hypertrophy is an affection of slow evolution and of unlimited duration, which, in its multiple stages, requires a treatment suitable to each one, and, although I am far from being a partisan of palliative operations in this particular class of cases, yet at the same time I feel that the operation of suprapubic cystotomy, which has been much abused, as well as neglected, has its field in certain instances. Dr. Gouley, in his recent and excellent book, entitled "Surgery of the Genito-Urinary Organs," expresses himself as follows: "Suprapubic drainage is necessary when catheterism becomes difficult or impossible. This drainage has been accomplished by simply puncturing the bladder and establishing a fistula, or by a systematic epi-cystotomy, as the late Hunter McGuire has done so successfully in many cases. Men in feeble health, who at no time were in condition for a radical operation, have survived these processes for years, with but little inconvenience." This sizes up the question.

In November, 1905, I was asked to see a man, sixty-nine years of age, on account of chronic urinary retention. The history of the case is briefly as follows: the patient had always been a thin although wiry man, but has never enjoyed robust health. The disturbances of micturition dated back some eighteen years, at which time he commenced to urinate more frequently than usual and the quantity voided at each micturition was rather small in amount. For the first three or four years he apparently did not suffer from nocturnal micturition, but little by little this developed, so that the patient was obliged to arise two or three times in a night. About three years before seeing this patient he had consulted an excellent physician, who had diagnosed prostatic hypertrophy with residual urine and had instructed the patient in the use of the catheter. He followed his physician's directions for a certain time, and having been considerably alleviated from his symptoms after a number of months, he neglected the use of his instrument.

When I saw the patient the first time, he was urinating six or seven times during the day, and three or four times during the night, the act being accompanied with considerable straining. In the intervals, the patient said that he passed urine involuntarily, and, as will be shown, this was merely due to overflow of a distended bladder from chronic retention. Occasionally, in the evening, the patient experienced slight chills, he complained of ardent thirst, tongue was dry and digestive disturbances were evident.

Upon rectal examination the prostate was found enormously developed, at least the size of an apple, but its surface was smooth and in consistency it was everywhere equal; in other words, the hypertrophy was regular.

Exploration of the urethra with a bulbous bougie, No. 22 French, showed that the instrument passed the entire length of the canal up to the prostate without any evidence of stricture, but when an endeavor was made to enter the bladder, it was practically impossible without the use of undue force to make any instrument enter.

The patient complained of much hypogastric pain, which had been present for five days previously and was increasing, while by percussion, the bladder was found distended to within two fingers' breadth of the umbilicus.

The patient both from the temperature and pulse, as well as the general symptoms present, including his age, was looked upon as a very poor surgical risk, but, to save life, it appeared evident that some interference must be undertaken, in order to relieve the sepsis, which was undermining the patient's strength. After deliberation, I decided to perform suprapubic cystostomy, which was done the following morning, Nov. 17, 1905.

The patient having been fully prepared the afternoon before, ethyl-chloride-ether narcosis was administered; the bladder was rapidly opened and stitched to the skin, the entire interference lasting seven minutes. As the subject was thin, the operation was exceedingly easy.

On the next day the temperature had fallen to normal, while the pulse, which had been about 100 and very wiry in character, had become fuller and beat 72. The expression of the patient was also much better. Irrigation of the bladder, with a 1-3000 solution of silver nitrate.

The sutures were removed on the sixth day, when perfect union of the artificial meatus was found to have taken place.

The patient lived eighteen months after the operation in a very comfortable condition, having had a suitable apparatus made for the hypogastric meatus. He died from cerebral hemorrhage. No autopsy could be obtained.

One word now as to the technic which I deem should be employed in these cases. First of all, given the age of these subjects and their very low vitality, operative rapidity is of paramount importance and, therefore, the procedure should be as simple as possible.

Like any operation the patient should, if possible, be properly prepared. The large intestine should be emptied by a copious enema and the field of operation thoroughly shaven and treated as for any ordinary laparotomy. After narcosis is obtained, the patient is placed in Trendelenburg position and, if the bladder is not distended with urine, it should be filled with a solution of boracic acid. Of course, when the organ is distended, this is not needed. I have always considered that the use of Peterson's bag was both useless and dangerous.

The incision should be made in the linea alba, measuring from 6 to 8 cm. in length and carried down to the pubic bone. The linea alba is then incised to almost the extent of the cutaneous incision, but in order to avoid involving the peritoneal cul-de-sac, it is more prudent to stop the incision a few millimeters below the skin incision. When the linea alba and transverse fascia have been incised, the left index should be introduced into the prevesical cellular tissue behind the posterior aspect of the pubic bone, down to the neck of the bladder. Occasionally, on account of the tension of the abdominal muscles, or when the bladder is deeply seated, a certain amount of dissection with the finger may be necessary. A bladder distended by retention is easy to recognize on account of its reddish muscular fibers. The peritoneal cul-de-sac is pushed upwards and retained in this position by the left index finger.

The question now comes up as to whether the bladder should be first opened or a cystopexy done, in order to prevent the urine from escaping into prevesical cellular tissue, and to settle this I would say that all depends upon the condition of the bladder. A bladder which is not too distended will have thick walls, and in this case it is better to do cystopexy first, while in cases of complete retention the bladder, being greatly distended, possesses thin walls and one would, from this fact, be liable to penetrate directly into the bladder cavity with the needles, thus giving exit to the urine. Consequently, in these cases, it is preferable to incise the bladder first and afterwards to suture it. A point which should not be neglected, is to make the incision into the bladder in the neighborhood of the neck, as McGuire recommended. After the bladder is opened the finger is introduced in order to explore the cavity and ascertain the condition of the prostate. When the bladder is emptied it should be thoroughly irrigated. Six sutures are sufficient to hitch the borders of the organ to the skin, and these should include the aponeurosis, the internal border of each rectus, the subcutaneous fat and the skin. When the opening in the bladder is made near the neck and when the cellular tissue is thick, it is perhaps better to merely include the skin in the sutures. The sutures should not be too tight and the coaptation should be made with as much care as possible.

The after-treatment should consist in irrigations of the bladder, and a proper apparatus for drainage established, so that no urine will soil the wound. There are plenty of excellent contrivances which constantly aspirate the urine from the bladder and thus keep the wound perfectly clean, and when attention is paid to this detail, the result in these cases will be most satisfactory.

To sum up, it may be said that suprapubic cystostomy should be resorted to in those cases where the patient is too feeble to undergo a radical cure of his prostatic hypertrophy and where the accidents of prostatism are serious. The operation is indicated when it is impossible to pass a catheter where there is acute retention in a mechanical prostatic, but this condition of affairs is rarely met with in practice. Usually, after suprapubic aspiration of the bladder, catheterism becomes possible and the permanent catheter will be sufficient. Pain, difficulty in catheterism, or the impossibility of the patient's tolerating the permanent catheter might also be indications for this operation. In acute and superacute infections, when the permanent catheter does not do away with the phenomena of infection, cystostomy should be undertaken in order to save the patient's life.

In the chronic form it occasionally is indicated when the permanent catheter does not influence the infection, or improve the general condition of the patient, or when accidents of sepsis reappear each time the catheter is removed. In old prostatics, the cystitides, rebellious to every treatment, require cystostomy, because the bladder pains cease as soon as the organ is opened. Abundant or repeated vesical hematuria places elderly patients' lives in danger and suprapubic cystostomy may frequently be of great service. In cases where calculi are present, especially when the bladder is infected, suprapubic cystostomy becomes both a curative and palliative operation.

Temporary cystostomy should usually be the end to be obtained and one should endeavor to re-establish the functions of the urethra as soon as the serious accidents have disappeared in cases of complete retention, hemorrhage and acute infection. The bladder pain, incomplete chronic retention, the permanent catheter which does not empty the fundus of the bladder, are all conditions which may be benefited by this operation.

Clinical Department.

CANCER OF THE MALE URETHRA. A REPORT OF TWO CASES.

BY J. DELLINGER BARNEY, M.D., BOSTON,
Assistant in Anatomy in the Harvard Medical School; Assistant Genito-Urinary Surgeon to the Boston Dispensary.

ATTENTION has again been called to that rare lesion, cancer of the male urethra, by an admirable article by Preiswerk.[1] In this article the disease is thoroughly exploited in every detail, and an exhaustive bibliography of the subject is added. Preiswerk gives a list of 39 cases, with a more or less complete history of each, which he considers to be undoubted examples of the disease. To this he adds three more cases, discovered too late to be tabulated, making his total 42.

In spite of his apparently complete bibliography, Preiswerk evidently failed to see an article on the subject by J. Basil Hall, of Bradford, England.[2] In this, Hall gives a list of 21 cases confirmed by microscopic examination, and 5 others which he classifies as doubtful because not so confirmed, making a total of 26. Of these, all but 6 are included in Preiswerk's list, so that the latter, with these 6 cases, makes, up to date, 48 reported cases of the disease.

Preiswerk's paper is exhaustive, and I shall not attempt to throw any further light on the subject. I do, however, wish to emphasize the fact that the disease is more often than not incorrectly diagnosed before operation, involving operative as well as prognostic blunders, while in many cases the real state of affairs has been discovered only after several operations have been performed. Of the 39 cases tabulated by Preiswerk, 21, or 54%, were regarded as cases of ordinary urethral stricture, either uncomplicated or, according to circumstances, attended with urinary extravasation, peri-urethral abscess, or urinary fistula. Among other diagnoses were syphilis of the urethra, and vesical or prostatic calculus. In 11 cases, however, a diagnosis of cancer of the urethra was made before operation. It is thus seen that the great majority of the cases, hardly any two of them seen by the same man, were not regarded so seriously as they should have been.

Preiswerk's cases also show that the symptoms are by no means uniform, or characteristic of a cancerous process. The fact that these symptoms and signs are such as might fit almost any case of stricture or calculus makes it all the easier to commit an error, especially in the prognosis, which may influence not only the future of the patient, but that of the surgeon himself. It is also a fact that cancer of the male urethra may appear in what we may term virgin soil, and for once the patient who denies venereal disease must be believed.

The two cases which I report are quite typical, in that the disease was primary in the deep urethra, and that, on microscopic examination, each proved to be a squamous cell carcinoma. Both cases occurred in the Massachusetts General Hospital, in the services of Dr. J. Collins Warren and of Dr. Arthur T. Cabot. I wish here to express my sincere thanks to these gentlemen for permission to report them.

[1] Ueber das primäre Karzinom der männlichen Urethra. Zeitschr für Urologie, 1907, Bd. I, Viertes Heft.
[2] Ann. Surg., Phila., 1904, vol. xxxix, pp. 375, 384.

CASE I. Service of Dr. J. Collins Warren. Age sixty-two, married. Occupation, farmer and artist. Birthplace, Germany. The patient first came to the hospital on Aug. 1, 1904, with the following history:

F. H. Unimportant.

P. H. Two years ago had sudden attack of retention of urine, lasting about five hours. No trouble after this for about a year. Since then has had several brief attacks of difficulty of micturition with dribbling, and was able to pass but a drop at a time. About seven months ago had chills every few weeks for about three months.

P. I. Five days ago had another attack of acute retention, lasting for about two days, when he again began to pass a little urine. Patient has been constipated for a long time, and feels much run down physically and mentally, he thinks from "overwork."

Patient denies venereal disease. Tobacco about ten cents a week. No liquor.

P. E. Well developed and fairly nourished. Reflexes normal. Nose clear, teeth poor. Nothing abnormal found in heart or lungs. Abdomen not remarkable, save for an enormously distended and tender bladder, which reaches almost to the umbilicus.

Marked edema of prepuce, with multiple strictures of urethra (size not stated).

At junction of scrotum with perineum is a marked wall of induration, extending to the posterior limits of the perineum, and apparently surrounding the urethra. *Rectal examination negative.*

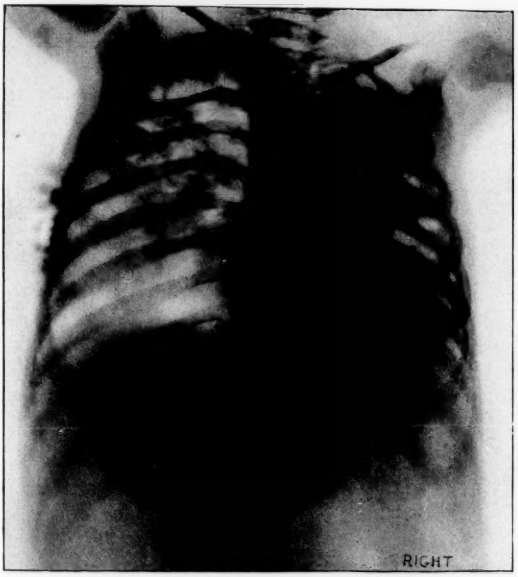
Perineal section was performed on Aug. 2, and the entire urethra made to take a No. 40 French sound. Convalescence was not remarkable, except that it was somewhat slow, and on Aug. 29, the patient was discharged to the Convalescent Home at Waverley, Mass.

At the end of about three weeks, the patient again came to the hospital for dilatation of the urethra. He still passed most of his urine through the perineal wound. General condition excellent. Sounds were passed under ether, and two weeks later the patient again went to the Convalescent Home, the wound being still open.

On Oct. 21, 1904, the patient was again sent to the hospital for further treatment. The urethra had again closed, and the perineal wound still remained open.

An operation was performed by Dr. Warren on Oct. 26. The perineal wound was enlarged by an incision three quarters of an inch long at each end in the median line, opening a cavity which was lined with indurated, grayish granulation tissue, looking suspiciously cancerous. Up to this time there was nothing in the appearance of the parts to suggest anything but an ordinary stricture of the urethra. The cavity was then thoroughly curetted, and a large sound was passed through the urethra into the bladder. A hasty examination of the curettings showed cancer, and no further operation was deemed advisable. The patient was put to bed, and put on constant drainage.

The subsequent history is as follows:



Oct. 30. Patient fairly comfortable, except for occasional pain in perineal wound, which was exquisitely tender. Granulations bright and clean. Urine clear and of good quantity. Catheter removed to-day. Bladder washed out with a solution of boric

acid three times daily. Slight edema of scrotum. Micturition entirely by perineal wound.

Nov. 3. Wound shows little tendency to heal, but looks bright and clean. Attempt to wash bladder via penis or perineal wound very painful. Micturition free through perineum.

Nov. 6. Complains of "stitch" in left side on deep inspiration. Examination shows only slight friction rub in left base in axillary line (cancerous pleurisy?).

A CASE OF ACQUIRED DEXTROCARDIA — YOUNG

A case of acquired dextrocardia associated with advanced phlebitis.

removed with scissors. Perineal stricture cut, and catheter tied in bladder.

Aug. 10. Bladder washed with boracic acid solution. Considerable urine still comes through perineal opening:

Aug. 14. Very little leakage.

Aug. 27. Catheter removed. Urine still comes freely through perineum, but also to some extent through the penis.

Aug. 28. Patient discharged against advice.

Pathological report by Dr. William F. Whitney, on specimen removed at operation:

"Mass which had grown from the urethra into a wound made for perineal section.

"Composed of masses of epithelial cells, many imbricated, and some showing fatty degeneration, separated by firm bands of connective tissue.

"Epithelioma."

Diligent search of state and town records and correspondence with local authorities, has failed to elicit any further information about this man. I have , but the time and cause of

incomplete cases, and the in any way to put the ıard, this paper will have

should have been.

Preiswerk's cases also s
are by no means uniform
cancerous process. The fact that these symptoms and signs are such as might fit almost any case of stricture or calculus makes it all the easier to commit an error, especially in the prognosis, which may influence not only the future of the patient, but that of the surgeon himself. It is also a fact that cancer of the male urethra may appear in what we may term virgin soil, and for once the patient who denies venereal disease must be believed.

The two cases which I report are quite typical, in that the disease was primary in the deep urethra, and that, on microscopic examination, each proved to be a squamous cell carcinoma. Both cases occurred in the Massachusetts General Hospital, in the services of Dr. J. Collins Warren and of Dr. Arthur T. Cabot. I wish here to express my sincere thanks to these gentlemen for permission to report them.

[1] Ueber das primäre Karzinom der männlichen Urethra. Zeitschr für Urologie, 1907, Bd. I, Viertes Heft.
[2] Ann. Surg., Phila., 1904, vol. xxxix, pp. 375, 384.

the median line, opening a cavity which was lined with indurated, grayish granulation tissue, looking suspiciously cancerous. Up to this time there was nothing in the appearance of the parts to suggest anything but an ordinary stricture of the urethra. The cavity was then thoroughly curetted, and a large sound was passed through the urethra into the bladder. A hasty examination of the curettings showed cancer, and no further operation was deemed advisable. The patient was put to bed, and put on constant drainage.

The subsequent history is as follows:

Oct. 30. Patient fairly comfortable, except for occasional pain in perineal wound, which was exquisitely tender. Granulations bright and clean. Urine clear and of good quantity. Catheter removed to-day. Bladder washed out with a solution of boric

acid three times daily. Slight edema of scrotum. Micturition entirely by perineal wound.

Nov. 3. Wound shows little tendency to heal, but looks bright and clean. Attempt to wash bladder via penis or perineal wound very painful. Micturition free through perineum.

Nov. 6. Complains of "stitch" in left side on deep inspiration. Examination shows only slight friction rub in left base in axillary line (cancerous pleurisy?). Pain entirely relieved by tight swathe.

Nov. 8. Pain in chest has disappeared. General condition about the same. Locally no induration about wound but finger introduced into it comes in contact posteriorly with a rough, indurated mass. Urination entirely by perineal route, and under perfect control. Sounds up to No. 24 French passed easily and without pain or bleeding through entire course of urethra to bladder. Bladder washed as before. Slight cystitis.

Nov. 12. Patient was discharged relieved.

Pathological report by Dr. William F. Whitney:

"Fragments curetted from the urethra showing, on microscopic examination, solid masses of large, flat, epithelial cells, with occasional whorls infiltrating the deeper tissues.

"Epithelioma."

A letter from the town clerk of Marshfield, Mass., where the patient lived, states that he died on March 30, 1905 (eight months from time of entrance), of cancer.[3]

Case II. Entered July 26, 1889, in the service of Dr. Arthur T. Cabot. Age fifty-eight years, single. Occupation, farmer; born in England; family history not recorded.

P. H. Gonorrhea fifteen years previously. Acute retention seven years later, relieved by catheterization by his physician. Since then has had more or less difficulty of micturition, with dribbling.

P. I. About one week before entrance noticed a tender bunch in the perineum.

Physical examination. Enters with an abscess in the perineum, size of a hen's egg, tender, red and painful. Patient thinks the abscess ruptured while on his way to the hospital. Pus and urine escape from the opening. No record of any rectal examination.

July 27. Operation by Dr. Cabot. Olive-tipped bougie shows tight stricture four inches from the meatus, just in front of the abscess. An incision through the abscess opens several pockets containing pus and cheesy material. A long urethral stricture was laid open, but the bladder could not be entered, owing to swelling of the tissues from edema and urinary extravasation.

Aug. 1. Good convalescence. Passing water freely through wound.

Aug. 6. Operation by Dr. Cabot. Director passed easily into bladder through wound, of which the swelling had now subsided. Some indurated, grayish granulations growing along urethra, and in perineal wound removed with scissors. Perineal stricture cut, and catheter tied in bladder.

Aug. 10. Bladder washed with boracic acid solution. Considerable urine still comes through perineal opening:

Aug. 14. Very little leakage.

Aug. 27. Catheter removed. Urine still comes freely through perineum, but also to some extent through the penis.

Aug. 28. Patient discharged against advice.

Pathological report by Dr. William F. Whitney, on specimen removed at operation:

"Mass which had grown from the urethra into a wound made for perineal section.

"Composed of masses of epithelial cells, many imbricated, and some showing fatty degeneration, separated by firm bands of connective tissue.

"Epithelioma."

Diligent search of state and town records and correspondence with local authorities, has failed to elicit any further information about this man. I have learned only that he is dead, but the time and cause of death are not known.

If these two somewhat incomplete cases, and the foregoing remarks serve in any way to put the general surgeon on his guard, this paper will have served its end.

[3] I was fortunate enough to have charge of this case as a house officer. After it was found that cancer was present, I made a thorough physical examination, with metastases in view, but none were to be found.

A CASE OF ACQUIRED DEXTROCARDIA ASSOCIATED WITH ADVANCED PHTHISIS.

BY J. HERBERT YOUNG, M.D., BOSTON.

Case 412. M. C., female. Age, nine years. Admitted to the House of the Good Samaritan Dec. 4, 1906.

Mother stated that the patient had coughed practically since birth, with expectoration for the past two years. There had never been any hemoptysis. Patient's father died of pulmonary tuberculosis, Dec. 28, 1906, after an illness of two years.

Physical examination of the chest was as follows:

Heart. — The greatest cardiac impulse was felt in the fifth space in the left mammary line 7 cm. to the left of the median line, and by percussion the left border corresponded. The right border could not be determined. No visible pulsation was noted. Heart sounds regular, of good quality, no murmurs.

Lungs. — The right side moved less. There was dullness throughout the right front, and behind from the apex to mid-scapula, and at the extreme base. Bronchial breathing at the right apex behind and in the second space right to the anterior axillary line, broncho-vesicular breathing elsewhere throughout the right lung. Scattered dry râles were heard throughout the right front and fine moist râles throughout the right back. There was no dulness on the left, but a few medium moist râles were heard at the apex behind.

Tubercle bacilli were present in the sputum.

Feb. 25, 1907. Heart. — Visible pulsation in the second, third and fourth spaces at the right border of the sternum. The greatest cardiac impulse was felt in the fourth space, 2.5 cm. within the left mammary line, 4.5 cm. to the left of the median line, where the left border was found by percussion. The right border was 5.5 cm. to the right of the median and 1.5 cm. within the right mammary line. The upper border was at the third rib. The sounds were regular and there were no murmurs.

Lungs. — The examination of the lungs was the same, except there was bronchial breathing over the upper half of the right lung in front.

April 22, 1907. Heart. — Pulsation was seen in the first, second and third spaces in the right parasternal line. The cardiac impulse was best felt and the sounds heard loudest in the third space right, 1 cm. inside the mammary line, 6 cm. to the right of the median line. The borders could not be determined by percussion. There was pulmonary resonance over the normal area of cardiac dullness. The sounds were regular and there were no murmurs.

Lungs. — There was dulness throughout the right front and back with amphoric breathing and voice sounds above the right clavicle and in the outer half of the first, second and third spaces right; bronchial

to amphoric breathing at the right apex behind to the lower angle of the scapula, with increased voice sounds. A few dry râles were heard at the right base. Dulness at the left apex behind, with a few dry râles.

June 7, 1907. Heart. — Visible and palpable pulsation in the second and third spaces between the sternum and the right mammary line. The cardiac impulse was best felt in the third space in the right mammary line, 7 cm. to the right of the median line. The left border was beneath the sternum and could not be accurately determined. The upper border was at the second rib and the right border in the right mammary line. The sounds were regular and there were no murmurs.

Lungs. — Dulness throughout the right front, except slight resonance, not tympanitic, from the apex to the third rib external to the right mammary line, over which area there was amphoric breathing, voice sounds, and cracked pot percussion note. In the back there was dulness below the lower angle of the right scapula, fair resonance above, with bronchial to amphoric breathing. Fine moist râles were heard throughout the lower half of the right lung. There was no further involvement of the left lung.

This case is unique in that during the transposition of the heart from left to right it was continually under observation. The displacement was gradual and, as it became more marked, signs of cavity were elicited at the right apex. There were no subjective symptoms referable to the heart, and, except for rare intervals when the patient was confined to her bed for a day or two, with slight gastric disturbance, she was dressed and about the ward all the time without any discomfort. Nor was there any clinical evidence that the heart was not performing its function perfectly in its abnormal position. X-ray examinations were made, but owing to the involvement of the right lung, the right border could not be accurately determined, although the absence of the normal cardiac shadow to the left of the sternum is clearly shown in the accompanying print.

About twenty-five cases of acquired dextrocardia associated with chronic pulmonary tuberculosis, without the presence of fluid or air in the pleural cavities, have been reported, but in all the cases, with the exception of four, the displacement was complete when the case first came under observation. A. K. Stone [1] mentions two cases from the literature which were seen before and after the displacement, in one of them there was a cavity in the right lung. Dunham [2] reported two cases which were also seen both before and after the displacement, and in which the diagnosis was verified by x-ray. One of these cases later showed signs of cavity at the apex of the right lung. In all the cases the right lung was the site of chronic phthisis, with the left but little if any involved.

In the article already referred to, Stone mentions the presence of cavities as a cause of cardiac displacement, and cites cases, while in the other cases reported the displacement has been ascribed to the sclerosis of the right lung, together with compensatory emphysema of the left, that is, the heart is pushed as well as pulled over, and although in some of these cases cavities were described, their importance as an etiological factor was not considered. In the present case the cavity in the right lung, the loss of substance thereby producing a void into which the heart was aspirated, was considered the cause of the displacement. The rôle played by cavities was further emphasized by cardiac displacements of a less degree in three other cases. In two cases with a cavity at the left apex, the heart was pulled upward and outward. The third case showed, for over a period of many months, involvement of the entire left lung, but without signs of cavity, with the heart in normal position. In making a routine examination pulsation was felt in the fifth space 6 cm. outside the mammary line, 14 cm. to the left of the median line, where also the left border was found by percussion. From previous experience a cavity was suspected and was found just within the lower angle of the left scapula.

Stone's article has an extensive bibliography on the subject of cardiac displacements. Since its publication, a few single cases have been reported, but with the exception of Dunham's two cases, and one case reported by Lowenburg,[3] they have not been reported in sufficient detail to be of any value.

I am indebted to the visiting physicians of the House of the Good Samaritan for permission to report this case, and to Dr. A. W. George, the Röntgenologist, for x-ray examinations.

Reports of Societies.

NEW ENGLAND OTOLOGICAL AND LARYNGOLOGICAL SOCIETY.

MEETING HELD AT THE MASSACHUSETTS GENERAL HOSPITAL, MARCH 15, 1907.

THE President, DR. A. COOLIDGE, JR., in the chair.

DR. A. P. ROGERS read a paper on

THE CORRECTION OF MALOCCLUSION AND ITS RELATION TO RHINOLOGY.[1]

DISCUSSION.

DR. THOMAS FILLEBROWN: I am happy to have the privilege of opening the discussion upon so interesting a paper, and I shall be glad to say a word to emphasize its good points if I can. What the essayist has said about the widening of the floor of the nasal cavity, I think to be true. One point I think needs a little more emphasizing.

The common idea in regard to regulating the teeth is that the crowns are simply turned outward, but that the ends of the roots are not moved. I think you will find that stated in a great deal of the dental literature as well as in the general medical literature. I think this is not true. The leverage as it is applied will not confine itself simply to the turning out of the teeth, but it will and it does, as has been proved by these cases that the essayist showed this evening, and by a great many others, actually widen the arch. The bones move apart and new bone is formed, not only in this

[1] See page 784.

one case that he mentioned, but in every case, so that there is a benefit rendered to the breathing power by enlargement of the nasal passages.

There is one point not mentioned in connection with the regulation of the teeth, — the influence of these irregularities upon the voice and articulation, as well as upon the looks of the patient. No person with upper front teeth that stand far out beyond the under, or with an under jaw so short that the under teeth are far back of the upper teeth, can ever speak perfectly.

I think that for a full understanding of the subject in relation to the enlargement of the cavities and the relation of the teeth to abnormal conditions, it may be well to recall the circumstances of the development and eruption of the teeth. We know that in the uterine stage the dental follicle is formed at a very early period, and then it is simply a pulpy mass. Yet before birth that pulpy mass has resolved itself into a well-formed sac, and in the lower part of it is a little bony substance, which proves, when it is erupted, to be the crown of the tooth. All above that crown of the tooth is in a pulpy mass. The crown is floating, in a sense; it has no power of resistance whatever. When it is erupted it is impelled forward by the nervous power of the system and not by any mechanical force. The root is formed as the crown moves forward; the distal end of this sac is all open, soft, pulpy, until the root is completed and has no power to resist anything.

At one stage of the progress a little follicle is given off from the sac, and becomes the germ of a permanent tooth and rests there under the same conditions as the germs of the temporary teeth. Then at from six to eight years old the temporary teeth are shed; how is that done? Not by any mechanical force; Nature has got ready for it to take place, and Nature is prepared to do the operation. She does it by being stimulated by the presence of the permanent tooth. What we call a carneous body, a fleshy body, is formed right on the spot where the absorption is to begin. Giant cells are very plenty there, and they go on and dissolve away that root as fast as the crown of the permanent tooth advances. Pretty soon it is all gone, and the temporary crown falls off for lack of support. But now supposing the crown of the permanent tooth does impinge directly on the end of the root of the temporary tooth, but on its side. In such cases we find the absorption takes place on the side, and may go on down to the crown, and the other portion of the root will remain. In such a case the eruption of the permanent tooth may take place and the temporary tooth still remain. Neither the temporary nor permanent set offers any mechanical resistance, and extracting only occasionally affords any relief. Another circumstance should be remembered: that as the permanent teeth are erupted, the alveolar wall is built up around the roots to hold them. The roots are not erupted through the bone, but the bone is formed after the teeth are erupted. When that temporary tooth is shed, the temporary alveolus is all absorbed and carried away and the permanent tooth comes out on a larger arch into new position, new bone is formed around it making a new alveolus to sustain it.

The question arises in the case of the deformities we have seen here, Are the teeth deformed because of the deformity, or is the deformity the cause of the non-eruption of the teeth? A case shown here to-night, where the third molar was impeded in its eruption by its impinging against the second molar, shows very plainly that in that case it was the malposition of the germ of that tooth, and its inability to move on as Nature intended, that made the trouble. So with another one, I think Dr. Mosher showed it, where the cuspid tooth was deformed and non-erupted. Now that tooth, when it made this trouble, was not exerting any pressure whatever, but its very presence by being mal-posed produced the irritation.

In these deformities the type is imperfect, it is not all acquired. These jumbles which were shown to-night were not acquired by mechanical pressure but by a variation of a type. You have too small a jaw for too many teeth and they cannot all get out and are held back. It is a question in my mind whether these deformities are caused by the teeth or the deformities cause the non-eruption of the teeth. As I remarked a little while ago, it is the tooth first and the alveolar walls afterwards.

I believe that the development of any tissue out of place, out of its proper relations, is almost sure to produce finally an irritation; this is true of the teeth.

Dr. H. P. Mosher: In six weeks I was able to find practically fifty cases of delayed eruption of the incisor teeth. In all of them, not only were there anterior ridges and spurs but also an anterior deviation of the septum. I feel, therefore, that delayed eruption of the incisor teeth must be considered as having a permanent place as one of the causes for deviations of the septum. The reason for this is as follows: the incisor teeth are imbedded in the premaxillary bones, two for each premaxilla. From the upper face of each premaxilla spring two small vertical processes which together make a V and hold between them the tip of the vomer. The vomer at birth consists of two leaves. The premaxillary wings act as cleats to control the position of the vomer. If these cleats are disturbed, the tip of the vomer is thrown out of line, and one or both of the leaves of the vomer are broken, and the cartilage which they hold is dislocated. Directly underneath the premaxillary wings and separated from them by very thin bone, are the central incisor teeth. It is found in the clinic that when there is marked delay in the eruption of one second central incisor, on the side of the delayed tooth the premaxillary wing is enlarged. Owing to this, the groove made by the premaxillary wings is distorted and the hypertrophied premaxillary wing pushes the tip of the vomer out of its true line. This results in a spur along the upper border of the vomer as well as in a deviation of the septum.

As the central incisors play such a prominent part in connection with deviations of the septum, I was extremely interested in what Dr. Rogers had to say about his ability to regulate the central incisors and to get them into place at the proper time.

The point which he brought out, that it is easy by changing the angle of the teeth to widen the nasal fossa, is very important. I should like to have this definitely proven. In order to do this the dentists and the rhinologists, as Dr. Rogers said, should work together. You can change the form of the alveolus by changing the angle of the teeth. Is there an equal change in the nose? Dr. Fillebrown says that there is. As yet I have not seen it.

Dr. Bogue, of New York, recently has been working with one of the rhinologists there on a case of this kind. Unfortunately, his case is as yet incomplete. Cases of this kind are of the greatest interest. We need accurate knowledge from accurate measurements, measurements of the nose as well as measurements of the jaw, not the vague statements which we have had in the past. It seems that we are on the point of getting this knowledge.

Dr. E. E. Foster: Many of the persons we see with a deformed superior maxilla are mouth breathers. The question of the relation between the two is as yet unsettled.

Some are of the opinion that mouth-breathing causes the palatal deformity, while others, especially Siebenmann and his scholars, contend that the deformed arch is only a part of a congenital narrow skull which caused the mouth-breathing.

From the literature and clinical evidence it seems reasonable to conclude that mouth-breathing produces the greatest number of deformed superior maxilla; a congenital or "inherited" narrow skull causes a lesser number, and rickets and allied processes produce the least number.

If it be true that mouth-breathing does cause deformities of the superior maxilla, then it is necessary first to establish good nasal respiration before the orthodontist begins his work.

On the other hand, the cases with a congenital narrow nasal cavity cannot be made good nasal breathers, without a sacrifice of normal tissues, until the orthodontist has widened the arch, which procedure widens the nasal cavity. This is a clinical fact observed for about twenty years.

Schroeder was the first to call attention to it.

It therefore appears that the orthodontists and rhinologists should work more or less together in these cases.

Intranasal measurements, referred to by Dr. Mosher, have not, so far as I can find, been made in connection with the widening of the hard palate.

From a suggestion made by Dr. Potter, of Boston, I have recently been able to prove in one case by intranasal measurements that a widening of the nasal cavity does occur after widening of the palate.

The second bicuspids were separated 7 mm. and the difference in distance between the inner surfaces of the inferior turbinates was 3 mm.

My method is to shrink the mucous membrane over the inferior turbinates with cocaine and adrenalin, then, with an instrument after the plan of an inside caliper, to measure the distances between the inner surfaces of the inferior turbinates at their middle third. This place can be selected with accuracy for future measurements by means of a bar at right angle to one of the caliper arms, which comes in contact with the upper lip at its junction with the nose. This bar indicates the distance the arms are in the nose.

DR. ALGERNON COOLIDGE showed a case of

GUNSHOT WOUND OF THE ANTRUM.

A small boy in taking part in an amateur performance had a gun loaded with wads accidentally discharged a short distance from his face. When first seen a few weeks later there was an extensive wound of the cheek, which had contracted leaving a fistula discharging pus, which was also escaping from the nares. Under ether it was found that the anterior wall of the antrum had been destroyed, also the wall between the antrum and the nasal cavity, most of the nasal septum and the neighboring ethmoid cells, leaving a large cavity representing both nasal cavities and the left antrum and ethmoid region. From this cavity eighteen gun wads were removed. That neither the orbital nor cranial cavity had been opened seemed almost miraculous. The detritus from the wound had been forced backwards, filling the posterior nares and naso-pharynx. This was cleaned away and nasal breathing re-established. No plastic operation to close the hole in the cheek was attempted, nevertheless this has closed of itself and leaves but a comparatively slight scar.

DR. J. P. CLARK showed

A CASE OF FRONTAL SINUSITIS OPERATED ON BY THE LUC METHOD.

For frontal sinus disease the Killian operation is the one now usually chosen because the ethmoid cells are affected, and in the majority of cases it is difficult to destroy them in any other way, but in a certain class of cases which are indicated by the x-ray plates, one can operate by the Luc method and destroy the ethmoid cells sufficiently to cure the cases. This can be done when the x-ray shows that a large opening can be established between the sinus and the nasal cavity.

The patient was a man twenty-seven years old, who was referred to me by Dr. Getchell, of Worcester, who had operated on him through the nose, and cleaned out the ethmoid cells as well as could be done through the nose; but the discharge still persisted and the frontal pain. He had been troubled with discharge from the nose and pain for rather an indefinite time, a number of years.

He was brought into the hospital and I operated on him on Feb. 14. Of course it is too early to see what the ultimate result will be; he has been very comfortable since the operation, the discharge has very much diminished, and the pain has ceased. An interesting feature of the case which was shown by the x-ray was that the sinus was divided by an almost complete bony septum. This was removed at the operation.

DR. MOSHER showed specimens in connection with the following cases:

EMPYEMA OF THE ANTRUM.

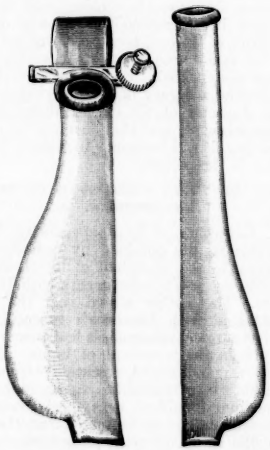
Some years ago the fact was demonstrated by Dr. F. C. Cobb and Dr. Thomas Fillebrown, both of Boston, that the antrum often acted as a reservoir for the frontal sinus. Since then we have gotten into the habit of considering many infections of the antrum as reservoir infections from the ethmoidal cells and the frontal sinus, occasionally forgetting the teeth as a common cause.

A recent case of mine illustrates this: The patient was a woman of fifty-six years, with a toothless upper jaw. Examination showed a foul discharge of pus from the right nostril and a large opening into the antrum underneath the inferior turbinate. About this opening there were many granulations. I operated without first taking an x-ray plate, the case was so clearly one of empyema of the antrum.

I operated feeling that I might run into malignant disease. Instead, in this toothless jaw, I found an unerupted canine tooth which was ulcerating forward through the canine fossa. This finding made what seemed likely to be a serious case a simple case. The root of the tooth acted as if it had more intelligence than the crown, because it had attempted to turn around and to go the right way, and to take the crown with it.

CARCINOMA OF THE LARYNX.

The specimen which is being passed round is the larynx as it was removed at the operation. The patient came into the accident room fighting for his breath, cyanotic and semi-conscious. It was possible to get a view of the vocal cords, and it was seen that they did not open. Dr. F. C. Cobb did a tracheotomy and relieved the case of its urgency. While the patient was under observation in the ward he got into trouble with the tracheotomy tube so that it had to be readjusted. After a short stay in the ward the patient was sent to the Throat Department. Here he was watched for a time by Dr. Cobb.



I operated about six weeks ago and found a very extensive case of malignant disease. In order to get beyond the growth it was necessary to take out the whole larynx and with it the trachea almost down to the sternal notch. The front wall of the esophagus was removed to the same point. At first the patient was

fed by rectum, and then after a few days through the tube which he wore in the esophagus. He did nicely.

The question now comes up as to the proper time for closing the wound in the floor of the mouth so that the patient may take his food in the natural way. Since so much of the trachea and so much of the front wall of the esophagus were removed, there was little tissue left from which to make a bridge between the two. If I close the wound in the floor of the mouth too soon, in an attempt to remake the anterior wall of the esophagus, and the patient should swallow by mouth and burst this open, the fluid will run into the trachea and kill him. At the present time the patient feeds himself by attaching a funnel to the rubber tube which he has worn in the esophagus since the operation. He cannot talk but speaks in a very loud whisper. After one has been with him a short time it is easy to understand what he says.

A DEVICE FOR INSERTING SKIN-GRAFTS IN THE RADICAL MASTOID CAVITY.

I wish to show a device which I have tried of late at the Eye and Ear Infirmary. It is a rubber bag so shaped that when it is distended with water it takes the form of the cavity made in the temporal bone by

the radical mastoid operation. It is designed to replace the gauze plug for holding a skin-graft in position. In order to use it the graft is cut in the usual way. One or two layers of gauze are put over the bag and over these the silk tissue bearing the graft. The bag is inserted in the ear, is distended with sterile water, and the end of the bag clamped. The bag is worn the usual length of time. Then the clamp is removed, the water let out, and the bag withdrawn. I have used this balloon graft-carrier with success.

In using the bag it is necessary not to distend it to such an extent as to give undue pressure on the walls of the canal. By using the bag most of the packing usually employed in the ear can be done away with. For instance, instead of filling the radical cavity with twenty or thirty small pieces of gauze, three or four pieces can be used for the Eustachian tube, and the rest of the cavity plugged with the bag. The bag can be used to hold in place the ordinary flaps made from the canal walls.

Dr. Coffin showed x-ray plates of a

CASE OF CYST,

which occupied practically the entire antral cavity. A canine tooth was removed through an incision in the canine fossa, the wall of the cyst was partly curetted away and drainage established through the nose.

INTERNATIONAL DERMATOLOGICAL CONGRESS.

Sixth International Dermatological Congress, Held at the Academy of Medicine, New York City, Sept. 9 to 14, 1907.

First Day, Monday, Sept. 9. Morning Session.

The President, Dr. James C. White, of Boston, in the Chair.

After the report of the Secretary-General, Dr. J. A. Fordyce, of New York, and the confirmation of officers, the following addresses of welcome were delivered:

FOR THE UNITED STATES GOVERNMENT.

Surgeon-Gen. P. M. Rixey, United States Navy, representing President Roosevelt, extended a most cordial welcome to the Congress, especially to the delegates from foreign countries, and he expressed the hope that the occasion would be the means of forming many ties that might be mutually beneficial. The coming together of such a body of men, experts in learning and specialists in the great field of dermatology, could not but be productive of much good to suffering humanity, not only of this but of every country here represented. The speaker said that in his naval medical work he had found, upon investigation, that the proportion of dermatological diseases to all others was about 13%. This showed clearly how important the subject was, and in the post-graduate medical school of the United States Navy at Washington more and more attention was being given to skin troubles, both in their didactic teaching and in the laboratory, and many of their most interesting reports were on that subject, especially in connection with tropical medicine.

FOR AMERICAN UNIVERSITIES.

President Ira Remsen, of Johns Hopkins University, said he esteemed it a great honor to be permitted to appear before this Congress and express a welcome on behalf of the universities of this country, and he sincerely hoped that the work of the Congress might in every respect prove profitable and pleasant. The universities were the training-schools of research. This fact had come to be recognized in medical circles in this country, and there was at present a well-defined university movement among the medical schools. The universities were taking possession of the medical schools and the latter were trying to get under cover of the universities, although the speaker said he was afraid that there would not be enough universities to go around.

FOR THE MEDICAL PROFESSION OF THE UNITED STATES.

Dr. Joseph D. Bryant, of New York, president of the American Medical Association, said the members of the American Medical Association were always glad to extend a cordial fraternal welcome to all those who labored in the advancement of medical attainment and for the relief of human affliction.

ADDRESS BY THE PRESIDENT OF THE CONGRESS.

Dr. James C. White, of Boston.[1]

[1] See Journal, Oct. 17, 1907, p. 513.

AFTERNOON SESSION.

DR. EDWARD L. KEYES, of New York, vice-president, in the chair.

LEPROSY: PROPOSALS FOR DIMINISHING THE DIFFUSION OF THE DISEASE.

PROF. R. CAMPANA, of Rome, Italy, in this paper, said that local treatment was necessary in leprosy in the initial stages of macular and tubercular symptoms. These could be arrested by radical surgical treatment, followed by cauterization. Tubercular leprosy was a purely local disease of much gravity, and its contagiousness, which had been proved experimentally, was in direct proportion to the shortness of the time that the malady had lasted. Hence the radical treatment of the disease was to destroy its manifestations as soon as they appeared. Hence the treatment of patients in whom these lesions had occurred ought to be directed towards diminishing the injurious effects of these trophic changes, more particularly those of the joints, to prevent breaches of surface, and to arrest the continuance of sources of sepsis in the individual patients and in their houses and in leper asylums.

DR. DOUGLASS W. MONTGOMERY, of San Francisco, said he did not understand Professor Campana's point of view that a patient, when once discovered to have leprosy, was no longer a menace to society. As a matter of fact, it was frequently difficult to establish the source of infection, and personally he could recall but a single instance where he was able to do it. So far as the first evidences of leprosy were concerned, the physician rarely saw them. The early symptoms were such that the patient himself did not usually attach much importance to them, and it was only later, when the disease was well established, that medical advice was sought. A long period frequently elapsed between the initial symptoms of leprosy and a well-marked case of lepra.

DR. H. E. MENAGE, of New Orleans, said that in the majority of cases of leprosy the micro-organism was either not demonstrable or had lost its virulence in the trophic lesions. He recalled cases, however, that had apparently originated from late lesions of tubercular leprosy.

DR. WALTER REMSEN BRINCKERHOFF, United States Laboratory, Honolulu, said that in Hawaii leprosy had been kept under control for over forty years by means of segregation, and he had been struck by the extreme difficulty that had been encountered in persuading lepers to go into segregation. The popular conception was that when a patient once entered a leprosarium, it was to die, and this prejudice against these institutions should be overcome. People should be informed that proper treatment would render them more comfortable, even if it would not cure them. In this way only would it be possible to get hold of the cases early.

DR. ISADORE DYER, of New Orleans, said that the trophic lesions of leprosy were evidence of the fact that the disease was more or less effete. An observation of a number of cases in the lazaretto in Havana seemed to show that. They pointed with a large degree of suggestive argument to the fact that although that institution had existed for many years, there was not a single instance of infection occurring in the hospital itself. In Louisiana they had had since 1894 something like 240 cases under observation at various times, and the method of isolation practiced there had apparently not only reduced the number from year to year, but had reduced it to nearly one quarter what it was when isolation was commenced.

DR. PRINCE A. MORROW, of New York, said it would be a practical impossibility to isolate cases of leprosy only during the early stages of the disease, simply because in a large proportion of cases the disease remained undetected in those stages. Even in cases of tubercular leprosy there were certain prodromata or initial symptoms which might entirely escape observation, and the nature of which could not be determined with absolute certainty without a microscopic examination.

DR. H. RADCLIFFE-CROCKER, of London, England, said there were mild cases of leprosy in which the symptoms might continue for an interminable number of years, and some of these patients got quite well. Leprosy was by no means a hopeless disease, and in the mild nerve forms the prognosis was fairly good. At all events, the duration of the disease was so long and the symptoms so trifling that they scarcely incommoded the patient.

DR. BURNSIDE FOSTER, of St. Paul, said that his experience with leprosy among the Scandinavians, mostly Norwegians, had led him to recognize the communicability of the disease, but he believed that it was communicated with great difficulty, that it could only be engrafted upon a peculiar soil, and that there were many who could not be inoculated with it.

PROFESSOR CAMPANA, in closing, said he did not wish to have it understood that he was opposed to isolating cases of leprosy, because it was very difficult to state the exact time when the infective period of the disease disappeared. He simply wished to insist on the scientific accuracy of the observation that the infectious character of the disease disappeared with its full development, and that in order to prevent it from spreading, it was necessary to destroy the sources of infection in the patient.

TREATMENT OF LUPUS VULGARIS WITH BERANECK'S TUBERCULIN.

DR. A. LASSUEUR, of Lausanne, Switzerland, said the favorable results obtained by radiotherapy and phototherapy in the treatment of lupus vulgaris had obscured the successful experiments with the various tuberculins. The author stated that the favorable results obtained with Béraneck's tuberculin in the treatment of surgical tuberculosis had encouraged him to employ it in the treatment of lupus. Béraneck's tuberculin, which differed essentially from Koch's, was a mixture of extracellular toxins prepared in a culture medium (bouillon) of a special composition, and of extracellular toxins extracted from the bacillary bodies by the action of ortho-phosphoric acid (1%). This tuberculin not only possessed immunizing properties, but it likewise exerted upon the Koch bacillus either a bactericidal action, when employed in concentrated solution, or a simple attenuating action when employed in dilute solution.

CONTRIBUTION ON THE NATURE AND TREATMENT OF LUPUS ERYTHEMATOSUS.

PROFESSOR CAMPANA and DR. G. LANZI, of Rome, Italy, presented a paper on this subject, in which they made the following statements: (1) That lupus erythematosus often became an incurable disease under the treatment at present generally used. (2) That there were cases of lupus erythematosus upon which tuberculin acted in the same way as it acted on true lupus. (3) That there were some cases not cured under the most active surgical treatment, but which were afterwards cured with surprising ease by the use of mercury ointment, which had been recommended by Hebra as most efficacious, although not proving so in practice in many instances. One must be guided

by an analysis of the conditions, in order to distinguish the special peculiarities forming the basis of the disease in each case. To begin with an injection of tuberculin and get no local or general reaction would certainly assign the case to a basis quite other than the tuberculoid predisposition accepted by many, but not admitted by all in lupus erythematosus. To begin with local and general treatment with mercury and obtain no apparent improvement therefrom would not predispose one to continue that method of treatment. In cases where the mercury had failed, and the tuberculin had given a positive reaction, local surgical treatment was possible; where the contrary happened, and the physician in charge had not attempted precautionary tests, local treatment was injurious and even disastrous.

Dr. M. B. Hartzell, of Philadelphia, said there was a certain number of cases of lupus erythematosus in which it was difficult to make the differential diagnosis between that affection and lupus vulgaris, and it was quite possible that a large proportion of the cases in which the tuberculin reaction was obtained were in fact lupus vulgaris rather than lupus erythematosus.

Dr. Stafford Taylor, of Liverpool, England, said the remedy in the treatment of lupus erythematosus that had proven most successful in his hands was pyrogallic acid. In the common or stationary types of the disease he used a 10% ointment of pyrogallic acid in the same way as he used it in lupus vulgaris.

Dr. Samuel Sherwell, of Brooklyn, N. Y., said that in cases of lupus erythematosus where the mucous membranes were not involved he had almost invariably obtained excellent results by the use of the curette, followed by the application of the acid nitrate of mercury.

Dr. Herman Lawrence, of Melbourne, Australia, referred to a method which he had found very successful and effective in the treatment of chronic lupus erythematosus. It consisted of scarification, followed by rubbing in iodoform, and then the application of a waxed India-rubber pad at moderate pressure, which was kept up for twenty-four to forty-eight hours.

ON THE VALUE OF AN ABSOLUTELY VEGETARIAN DIET IN PSORIASIS.

Dr. L. Duncan Bulkley, of New York, read a paper on this subject, in which he offered the following conclusions:

(1) The cause of psoriasis was as yet unknown. Many facts pointed to its not being a purely local disease of the skin, although the character of the individual lesions strongly suggested a parasitic element in their production; possibly one of the ordinary micro-organisms, universally present, took on a pathogenic action when the soil was suitable. (2) Psoriatic patients often appeared to be in perfect health, but metabolic disturbances could generally be discovered by complete quantitative urinalysis. (3) The error was generally along the line of faulty nitrogenous metabolism and diminished excretion of the purin products. (4) Long observation of cases showed a decided increase of eruption with excessive meat eating. (5) Marked improvement in the eruption occurred under the same treatment when a strictly vegetarian diet was faithfully carried out. (6) Continued strict vegetarian diet was often attended with freedom from eruption, and relapses were often directly traceable to dietary errors in this direction. (7) This was the experience of the writer with this plan of treatment in private practice for twenty years.

Dr. H. Radcliffe-Crocker, of London, said he had seen psoriasis in vegetarians and in butchers, and he had arrived at the conclusion that diet had very little influence upon the course of the disease. His conclusions in regard to the influence of diet upon psoriasis were totally unlike those of Dr. Bulkley. Of course, in cases occurring after middle life, in patients with an undoubted gouty tendency, the proper restriction of the nitrogenous food was certainly indicated, but a study of the age at which psoriasis frequently made its appearance showed that fully two thirds of the cases had their onset before the age of thirty; that is, during a stage of life when errors in metabolism were comparatively few.

(To be continued.)

Book Reviews.

Surgery: its Principles and Practice. By various authors. Edited by W lliam Williams Keen, M.D., LL.D. Vol. II. Ilustrated. Philadelphia and London: W. B. Saunders Company. 1907.

It is a pleasure to be able to continue our very favorable criticism of Keen's surgery. Volume II presents the same virtues of the art of bookmaking which characterized Volume I. It is, moreover, a slightly smaller book, for which the editor is to be congratulated. The pictures are uniformly extremely good, appropriately chosen, and in many instances deserve unstinted admiration; to an unusual degree they literally illuminate the text.

Certain chapters demand particular praise. Diseases of bones, by Dr. Nichols, seems to us the most complete, concise and convincing treatment of the subject that has appeared in America. The same is true of his pathology of the joints; indeed, the latter may in the opinion of many excel even the former chapter; the pictures are superb. The clinical part of joint surgery is acceptably written by Dr. Lovett; it is certainly a very difficult task to gather into 70 pages the essentials of such a subject, even though an additional chapter, one third longer, is devoted to orthopedic surgery exclusive of joints. This latter chapter, also by Dr. Lovett, seems to us extremely good; it has also been condensed, but a proper proportion of its various divisions has been maintained; the style is lucid, the illustrations plentiful and well adapted to the text.

The long chapter (210 pages) on fractures, and one on dislocations (60 pages) are of somewhat uneven character. In certain instances the treatment indicated does not seem to us ideal (*e. g.*, open treatment of fracture of the patella). Too little space is devoted to certain important general conditions. Fat embolism is given but 13 lines, and delirium tremens 20 lines in 210 pages, while a consideration of the ractures of carpal bones covers more than three pages, exclusive of pictures. Allis's method of reduction of hip-joint dislocations deserves more detailed consideration than is accorded to it. Nevertheless, these chapters are perhaps as good a presentation of the subject as we may expect under existing circumstances. Dr. Binnie's chapter on muscles, tendons and bursæ is particularly

satisfactory, and is written in a most attractive style. Its 34 pages contain all that is essential without evidences of crowding. The lymphatic system, by Dr. Gerrish, is interesting and sufficient, the pictures supplementing the text unusually well. In the otherwise excellent chapter on the surgery of the skin, treatment is frequently meager and unsatisfactory; many methods are mentioned without comment, and others, equally well known, are entirely omitted. Wright's vaccine for furunculosis receives one and one-half lines; no reference is made to Pfaff's fundamental researches on dermatitis venenata; none to the use of picric acid in burns; from a practical standpoint, a considerable elaboration of treatment would be desirable in this chapter.

The pathology of the nervous system, by Dr. Spiller, is an admirable section, embodying much of his own original work; it is beautifully illustrated, and unquestionably is one of the best chapters in the book.

Surgery of the nerves, and of the spine, two chapters by Dr. Woolsey, are completely satisfactory, among other things, his description of laminectomy, its indications and prognosis, is the best we have seen.

The Traumatic Neuroses, by Dr. Dercum, certainly gives us all that can be condensed into 30 pages, upon this most perplexing subject. It is to be commended for the fairness and common sense which are evident throughout its paragraphs. Dr. Da Costa adds a brief article on Surgery among the Insane; it is of undoubted value, and has been previously too much overlooked in textbooks: it is presented in an attractive and vigorous style.

An extensive and exhaustive index finishes this admirable volume.

Diseases of the Genito-Urinary Organs and the Kidney. By ROBERT HOLMES GREENE, A.M., M.D., Professor of Genito-Urinary Surgery, Medical Department of Fordham University; Genito-Urinary Surgeon to the City and to the French Hospitals, New York City; and HARLOW BROOKS, M.D., Assistant Professor of Pathologic Anatomy, University and Bellevue Hospital Medical School; Visiting Surgeon to the City Hospital, New York City. With 292 illustrations. Philadelphia and London: W. B. Saunders Company. 1907.

In their preface, the authors disclaim the intention of writing an exhaustive and complete treatise upon the subject with which their work is concerned, and thus disarm criticism with regard to this aspect of it, and leave the reviewer merely with the regret that they should not have made more complete a work which is in so many other respects admirable. As it is, it does not reach the general plane of excellence of some of the best publications which are devoted to this field, such as those of Frisch and Zuckerkand, in Germany, or of Keyes or White and Martin in this country.

The intention of the writers is stated to have been to devote equal attention to the medical and surgical maladies of the region with which the work is concerned. We do not think that they have thereby added to its value, although it cannot be denied that some of the parts devoted to the medical side of the subject are excellent.

As a bit of book making, the volume is somewhat disappointing, more especially in view of the high standard of excellence which its publishers have already attained in some of their other productions of medical literature. In this work there are a good many inferior, and but few really good, illustrations. This fact causes the book to lack the finished appearance which is rapidly becoming a *sine qua non* of surgical publications. It must be added, however, that up to the present time, no really well and handsomely illustrated work on this field of surgery, has been issued and the volume which we are discussing does not fall below the previously attained standards in this respect.

Other than this, the most conspicuous defect of the work before us is the entirely inadequate and scant manner in which many of the subjects are treated, thus, the entire subject of Renal Injuries is given less than three pages. Six pages include all that the authors have to say upon the subject of tumors of the kidney and their treatment, while the whole surgery of the kidney is compressed into about sixteen pages of print. The pathology of tumors of the bladder is discussed in two short paragraphs, while the treatment of this condition is dismissed in a couple more paragraphs, and three lines only are devoted to the question of the surgical treatment other than that of the removal of such growths by the but little approved method of Nitze's cystoscope.

This characteristic of too curt a consideration of some of the more important divisions of the work deprive it of a great part of its value in many of the sections which demand a full discussion, if they are to contribute anything of importance to the subjects.

Per contra the treatment accorded to certain other parts of the work is most satisfactory. Among them may be noted the sections on "Compensation in Renal Disease," "Uremia," "The Blood Pressure in Renal Disease," etc.

The Principles and Practice of Modern Surgery. By ROSWELL PARK, A.M., M.D., LL.D. (Yale), Professor of the Principles and Practice of Surgery and of Clinical Surgery in the University of Buffalo; Ex-President of the American Surgical Association; Surgeon to the Buffalo General Hospital, etc. With 722 engravings and 60 full-page plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co. 1907.

Roswell Park cannot fail to interest us whenever he writes for our instruction, and his present volume deserves special notice as the mature work of one of our most eminent American surgeons. It aims at being a complete treatise, in one volume, on the principles as well as on the practice of modern surgery. In his preface the author points out that a new work in surgery

enters a field of literature already rich in excellent books differing widely in plan and view point, and he remarks truly that when surgery can be represented by a conventional and well-settled type of book it will have ceased to advance. Accordingly, he sets out for us in a great volume of more than a thousand pages his matured views upon the whole subject of surgery.

The captious critic might assert that expert opinions on all the details of so extensive a science as surgery, as it exists to-day, cannot be held by a single human intelligence, and doubtless Park himself would admit the truth of this view. In spite of its sundry shortcomings, however, we cannot but regard this great work as an extremely important contribution to surgical literature, especially to the medical student's library.

The special trend of a writer's interest must develop itself in the construction of so extensive a work as the one we are considering. While Roswell Park is known to American surgeons as a sound practitioner and an able operator in many fields, he has become conspicuous especially for his interest in certain branches, and as a cultivated student of general surgical history and literature. Accordingly we find that he devotes 543 of his 1,048 closely printed pages to pathology, surgical diseases, surgical principles, the processes of repair and the affections of tissues, leaving 503 pages only for the consideration of special or regional surgery. The reviewer may therefore conveniently divide this book into two nearly equal portions, — that dealing with the theory and development of surgical affections, and that dealing with practical, clinical surgery. Probably such a division is fair and accurate, yet one cannot but feel at times that the second half of the book especially might have been elaborated into a subsequent and independent work. The interests of surgery have become so far-reaching in recent years, as Park himself points out, and the endeavors of surgeons are now so concerned with nearly every branch of medicine that one feels it to be almost impossible adequately to confine within two covers a treatise on so vast a subject. One discovers, therefore, on reading the present volume, that the first half is the more elaborate and satisfactory, while the second half, though interesting, is little more than an epitome.

This reviewer may not attempt to discuss in detail the immense wealth of material with which the author presents us, though it is proper to name two or three chapters of special interest. Chapter VI, on auto-infections in surgical patients, is peculiarly well worth reading, and the opening paragraph serves as its text: "One of the greatest advances made in pathology has been the establishment of the fact that a great many of the morbid conditions from which the human race suffers are those due to causes arising entirely from within its own system. . . . That these general facts have been recognized for centuries is perhaps a credit to the powers of observation of practitioners of past generations. Exact knowledge, however, has come only with exact methods of laboratory research. . . . The subject of *Auto-intoxication* has been too commonly relegated to the domain of internal medicine." The subject, "The Status Lymphaticus," engages our author's attention and he devotes his luminous Chapter XIV to that interesting and little understood topic. He gives us in Chapter XXII an extremely readable, unhackneyed essay on gunshot wounds, drawing largely upon American, English and Japanese experiences in recent wars, and illustrating his text with many new and striking pictures.

"*A tumor is a new formation, not of inflammatory origin, characterized by more or less histological conformity to the tissue in which it has originated, and having no physiological function.*" With that definition, Park enters upon his brilliant Chapter XXVI, into which he succeeds in condensing an astonishing amount and variety of valuable information. It is probably the most useful chapter in the book, and incidentally the author makes a plea for his own convictions regarding the *parasitic theory of tumor formation.*

The last half of the volume, though full of valuable and original suggestions and advice, is too crowded to admit of such interesting writing as emphasizes many of the previous chapters. Moreover, it must be that the author now finds himself dealing occasionally with topics which have failed to arouse his own enthusiasm. The chapter on the head, for example, though sound and conventional, by no means emphasizes the great part which experts now assign to cerebral surgery. That topic is dismissed with 47 pages. The breast, too, is somewhat slighted with a brief 12 pages, and the whole of the great and complex subject of "Abdominal Surgery" is summed up in 188 of the thousand pages which make up the book. But this is cavil, perhaps. Grievous are the limitations of space. One admits more fairly, and with generous appreciation, that the author's exposition and teaching, in this Part VI, show his wide experience, his extensive reading, his sound and judicious mind and practice. It is a pleasure to read and to review so admirable and useful a work.

Cure of Tetanus. — Within the past two months two cases of tetanus have been reported as cured at St. Michael's Hospital by means of hypodermatic injections of tetanus antitoxin.

Bequest to Peekskill Hospital. — Among other charitable bequests in the will of the late Mrs. Mary A. Frost, of New York, is the sum of $5,000 to the Peekskill Hospital, to endow a bed in memory of her mother, Mary A. Hart.

Retirement of Prof. C. A. Ewald from Editorship of the Berliner Medizinische Wochenschrift. — It is announced that Prof. C. A. Ewald, who has been one of the editors of the *Berliner Medizinische Wochenschrift* for upwards of twenty years, has retired, in order to devote more time to teaching and investigation.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 12, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

WALKING AND HEALTH.

IN 1867 a young man of twenty-seven years, Edward Payson Weston by name, walked from Portland in Maine to Chicago in twenty-four days and nineteen hours. This was then considered a remarkable feat. Yet, a few days ago (to be precise, on Nov. 27), this same young man — for he seems to have lost none of the vigor and freshness of youth — repeated his performance of forty years ago, gaining on it in point of time by twenty-nine hours. Some features of this amazing walk should particularly interest the medical man.

Weston did not reach Chicago a pathetic figure, doddering, footsore, gaunt and with sunken eyes, as has often been the case at the end of long-distance matches, a condition which might be expected in a man of seventy after so prodigious a task. On the contrary his step was sprightly as at the beginning; he finished lithe and sturdy; his wind was so good that while jogging on he laughed and chatted with his escorts, as he had done throughout all his journey, when he had oftentimes chaffed those who found it difficult to keep up with him beyond a short distance. Within a few days of the end he reeled off ninety-six miles in the twenty-four hours; and at the completion of the trip, in order to manifest his prime condition, he covered, without stopping to rest at all, forty-five consecutive miles.

Mentally his condition was throughout excellent, as was evidenced by the daily reports he found time to supply the *New York Times;* he sent excellent "copy," crisp, bright and interesting, in the best reportorial style. For Weston is not only a "walker"; he is a man quite sanely active in many things beside. He is of that ideal type, the man with an active brain in a sound body. It will interest our orthopedic colleagues that, as he states, he, early in the trip, sprained his ankle; he "walked this off," and soon all pain and discomfiture ceased from it. He ate frequently, as often as he was hungry; and let us assume that he was thoroughly Fletcherian in his mastication. An egg beaten in a cup of hot coffee was a favorite refreshment. When he felt drowsy he ate, and this, he declares, restored him. Frequent meals were essential; for such walking disposed rapidly of tissue elements, which had as rapidly to be renewed. Withal he lost from beginning to end but eighteen pounds.

Truly, this man has demonstrated the superlative excellence of walking as an exercise, especially when associated with good habits and temperate living. It is of all the cheapest, for little paraphernalia is required. It would rejoice us to return in this respect at least to the days of Blaikie, Hazlitt and wise old Samuel Johnson. It would undoubtedly require some little courage to re-establish this beneficent custom; to be seen upon the highways with a haversack upon one's back, comfortably adjusted with straps, and with it insulated bottles and compartments containing compressed food-stuffs. One must also risk a limb or perhaps one's life by collision with "devil-wagons." But for such trials one may find compensation. It is the simplest of all exercises, this old-fashioned brisk striding, head up, the arms swinging, the organs functioning normally, the whole muscular system being in play, while the mind is diverted by glorious and ever-changing scenery during the progress along winding roads. "Give me," wrote Hazlitt, "the clear blue sky over my head, and the green turf beneath my feet, a winding road before me, and a three hours' march; and then to thinking." Whereat Stevenson, "And he must have a winding road, the epicure."

Walking is also perhaps the wisest exercise to recommend to one's patients. In others,— boxing, tennis, weight throwing and the like, — what men do not become slower in their movements after thirty; who, even the most expert, would think, after fifty, of competing with young men in them? Besides, one has to train but little to get into condition for walking; five miles, not a step more, the first day, ten the next, fifteen the third, after which one is not likely to tire, no matter how long a day he puts in at it.

Finally, Weston has proved anew that man is not only the strongest animal in nature, but that he comes pretty near to being the strongest and

most enduring machine. His dispatches state that during one day a team which was accompanying him gave out after it had followed him for fifty miles. The animals stumbled in the road; nor could they proceed further until they had been allowed to rest in a stable. Some men who accompanied Weston in an automobile fared as badly; they were left behind, being exhausted as the result of exposure to the cold, while the walker strode along at an easy gait and without effort. It is well observed that a good horse, a good automobile and a properly trained man might start from the East for San Francisco. The first two would, of course, disappear before the latter had reached a milepost; but most likely the man would, somewhere this side the Mississippi, come upon the horse laid up in a boarding stable and upon the car towed to the repair shop with a wrenched axle. In the race for a month or a year man need not ask for a handicap from any other member of the animal kingdom; nor has he ever devised any machine which can transport him over obstacles and through diverse and difficult conditions as satisfactorily as his own legs.

STANDARDS OF ADMISSION TO MEDICAL SCHOOLS.

The agitation regarding the raising of the standard of admission to medical schools in this country has now been in progress for upwards of fifteen years. Beginning with the requirement of a bachelor's or equivalent degree by the Johns Hopkins school at its opening, about fifteen years ago, the university schools have followed its example, so that now a considerable number have a similar requirement for admission. The whole movement is in a measure a reaction from the deplorable condition into which medical education in the United States had fallen, regarding not only the requirement for admission, but also in relation to the amount of knowledge thought necessary for the attainment of a degree in medicine. The widespread protest against this easy road to professional recognition has resulted in a general and admirable elevation of standard in our best medical schools, together with a closer affiliation of medical school and university. The poorer schools have been forced either to close their doors or else meet in some measure the popular demand for a more adequate training of their students. The general effect upon medical education in this country has naturally been most salutary as shown by the greater productiveness of American students and investigators during the past decade than ever before.

One of the products of a clearer recognition of medicine as essentially a branch of university education has been the development of the Cornell University Medical College, one of the newest and most active schools in the country. We are interested in noting that very recently the announcement has been made that the ordinary high school education, hitherto regarded as adequate for admission, is to give place to a much more rigid requirement. On and after 1908 candidates for admission to this school must be (1) graduates of approved colleges or scientific schools; or (2) seniors in good standing in Cornell University or in any other approved college or scientific school whose faculty will permit them to substitute the first year of a professional course for the fourth year in arts and sciences, and who will confer upon them the bachelor's degree upon the satisfactory completion of the first year of the course in the Cornell University Medical College; or (3) persons who, while not possessing a bachelor's degree, give evidence by examination that they have acquired an equivalent education and a training sufficient to enable them to profit by the instruction in the medical college. In and after 1909 all candidates for admission to the medical college must have at least such knowledge of physics and inorganic chemistry as may be obtained in college by a year's course in these subjects when accompanied by laboratory work. In and after 1910 all candidates for admission must possess a similar knowledge of biology.

In these requirements, as there should be, considerable latitude is allowed, so that the medical course is not precluded for those who show themselves properly equipped, even although they may not have acquired a bachelor's degree. In the present state of academic training, as President Eliot has recently pointed out, the bachelor's degree in itself means little beyond four years spent in study of the liberal arts. It does not imply a training standing in definite relation to later work in medicine. It therefore becomes highly desirable that candidates for medical schools should have not merely a bachelor's degree, but a preliminary training of a sort which has a more definite relation to medicine than an ordinary college course implies. The University of Pennsylvania has been wise in increasing its requirements for admission to its medical school gradually, rather than in the more radical way which certain other universities have adopted. Cornell's plan is similar, aiming as it does toward

a preliminary course of study which lays stress upon quality rather than quantity.

In general, there is considerable evidence that the pendulum has swung back somewhat, and that educators are recognizing that graduation from a medical school at an average age of twenty-six, exclusive of hospital training, is too late. The problem therefore presents itself of making earlier graduation possible without detracting from the real equipment of the student. The experiment is now being tried in the West of prescribing a two-year preliminary course in biology, chemistry and allied subjects for those proposing later to study medicine, thereby making possible the attainment of a medical degree at twenty-four. It is becoming increasingly evident that whatever value an unsystematized college course may have as a general means of culture, it is not essential to medicine and may be positively detrimental in that it not only does not concentrate attention upon important preliminary branches, but delays entrance upon active and independent professional work. A modification of the loose requirement of a bachelor's or equivalent degree will no doubt come to be desirable in the near future. Our eagerness to raise the standard of medical education may be found to have over-reached itself.

MEDICAL NOTES.

DEATH OF PROF. MORITZ SCHMIDT. — The death of Prof. Moritz Schmidt, at Frankfort-on-the-Main, a laryngologist of some prominence, is announced.

AWARD OF THE NOBEL PRIZE IN MEDICINE. — The Nobel prize this year goes to France, the recipient being Laveran, whose name is familiar in connection with pioneer work on the subject of malaria.

AMERICAN DENTAL DEGREES IN GERMANY. — After many years' litigation, the German Courts have finally ruled that an American degree of dental surgery may hereafter be used in Germany when issued by a reputable American college of dentistry. Up to this time the American degree has not been recognized.

INCREASED ENDOWMENT OF THE CARNEGIE INSTITUTION. — At a meeting of the board of trustees of the Carnegie Institution held at Washington, Tuesday, Dec. 10, a letter from Andrew Carnegie was read in which he said he had decided to add $2,000,000 to the endowment of the institution.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Dec. 11, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 59, scarlatina 35, typhoid fever 6, measles 20, tuberculosis 71, smallpox 0.

The death-rate of the reported deaths for the week ending Dec. 11, 1907, was 23.10.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, Dec. 7, 1907, was 216, against 254 the corresponding week of last year, showing a decrease of 38 deaths and making the death-rate for the week 18.48. Of this number 103 were males and 113 were females; 210 were white and 6 colored; 119 were born in the United States, 92 in foreign countries and 5 unknown; 39 were of American parentage, 153 of foreign parentage and 24 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 57 cases and 2 deaths; scarlatina, 49 cases and 0 deaths; typhoid fever, 10 cases and 1 death; measles, 23 cases and 0 deaths; tuberculosis, 45 cases and 16 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 44, whooping cough 0, heart disease 29, bronchitis 11 and marasmus 2. There were 16 deaths from violent causes. The number of children who died under one year was 24; the number under five years, 40. The number of persons who died over sixty years of age was 66. The deaths in public institutions were 68.

There were 2 cases and 2 deaths reported from cerebrospinal meningitis during the week.

A CENTENARIAN. — Mrs. Deborah A. Kendall has recently died in Pittsfield, Mass., at the reputed age of one hundred and one years, her death being attributed to old age.

DIPHTHERIA AT TEWKSBURY, MASS. — It is reported that a somewhat extensive epidemic of diphtheria has appeared among the attendants of the Tewksbury, Mass., Almshouse. Up to this time the disease has been practically confined to the nurses, and there seems no reason to anticipate that it will extend to the patients.

EXAMINATION OF MASSACHUSETTS STATE BOARD OF REGISTRATION IN MEDICINE. — At a recent examination of candidates by the Massachusetts State Board of Registration in Medicine, 48 of 84 applicants received certificates. The proportion of rejected candidates was somewhat larger than usual.

NEW YORK.

Fire at the New Jersey State Hospital for the Insane. — During the night of Nov. 27, the nurses' building of the New Jersey State Hospital for the Insane, at Morris Plains, was almost completely destroyed by fire. The rapid spread of the flames cut off the escape of the nurses sleeping on the third floor, and three of them were injured (though none fatally) by jumping from the windows.

Gold Medal from the Jamestown Exposition to Mrs. Henry Parsons. — The jury of awards of the Jamestown Exposition has awarded to Mrs. Henry Parsons a gold medal for a series of photographs illustrating the work of the first children's school farm in New York City, established by her. The farm is located in De Witt Clinton Park, on the shore of the Hudson, and has proved of great interest to the children of the public schools.

The Physicians' and Pharmacists' Mutual Aid and Protective Association of New York County. — On Dec. 6, a number of east side physicians and druggists met and organized a new society to be known as The Physicians' and Pharmacists' Mutual Aid and Protective Association of New York County. Among the objects of the society are the discouragement of the practice of treating the members of lodges for a small uniform fee, of the sale of patent medicines and of the taking advantage of the free dispensaries by persons able to pay for medical treatment.

Work for the Blind. — At a meeting of the League of Political Study on Nov. 26, Miss Winifred Holt, secretary of the New York Association for the Blind, made an interesting address in which she described the efforts of the association to make blind persons self-supporting. In the course of it she related how five sightless operators had been successfully trained for telephone switchboard work. She also expressed the opinion that the field of stenography was an admirable one for the blind, and stated that on the staff of the association there was a blind stenographer who, she found, made fewer typographical errors than any of the others. Incidentally, she compared the manner in which blind children were cared for in Boston and New York, rather to the discredit of the latter city, and said that it was the duty of every citizen to demand that these unfortunates in New York should have the same advantages as those in Boston. Miss Holt is a daughter of Henry Holt, the publisher, and it is largely due to the personal efforts and generous gifts of herself and her sister that the association has been able to accomplish all the good which it has.

Mortality Reports for November and the Week. — The weekly reports of the Health Department show that during the month of November the mortality in the city represented an annual death-rate of 15.87, as against 16.20 in October and 16.61 in November, 1906. Among the diseases in which there was a diminished fatality were the following: the weekly average of deaths from typhoid fever decreased from 24.75 in October to 19 in November; the weekly average from whooping-cough, from 3.75 to 2; from epidemic cerebrospinal meningitis, from 7.5 to 6.75; from diarrheal diseases, from 114.25 to 47; from diarrheals under five years of age, from 107.5 to 40; from cancer, from 62.5 to 56.75; from apoplexy, congestion and softening of the brain, from 51.75 to 45.75; from organic heart diseases, from 145.25 to 140; and from cirrhosis of the liver, from 22 to 16.75. Among the diseases in which there was an augmented mortality were the following: the weekly average of deaths from measles increased from 4.75 to 7.5; from scarlet fever, from 8 to 13; from diphtheria and croup, from 25.5 to 29; from influenza, from 3.75 to 5.25; from pulmonary tuberculosis, from 150.5 to 154.5; from acute bronchitis, from 13.5 to 19.5; from lobar pneumonia, from 84.75 to 116.25; from bronchopneumonia, from 72 to 99; and from Bright's disease and acute nephritis, from 94.75 to 99.5. It is worth noting that during the first week in November the deaths from epidemic cerebrospinal meningitis, for the first time perhaps in two years, were only three in number. Later in the month, however, the deaths from this cause increased, and in the week ending Nov. 30, they amounted to 12. The corrected November death-rate (excluding non-residents and infants under one week old) reached the low figure of 14.85.

Mortality Report for the Quarter. — The last condensed quarterly report of the Bureau of Records of the City Health Department, for the quarter ending Sept. 30, 1907, shows that the death-rate in the quarter was 18.66 per 1,000 of the population, as against 18.51 for the corresponding quarters of the preceding five years; an increase of .15. Comparing the number of deaths from the principal causes and at certain age-groups with those of the preceding quinquennial averages of the corresponding quarters, the

following decreases are found: typhoid fever, 52; malarial fever, 4; smallpox, 7; whooping-cough, 10; diphtheria and croup, 30; pulmonary tuberculosis, 149; all other forms of tuberculosis, 6; meningitis, 93; apoplexy, 86; acute bronchitis, 109; lobar pneumonia, 114; Bright's disease and acute nephritis, 175; old age, 59; sunstroke, 53; suicide, 21; between the ages of five and sixty-five years, 39. The following increases are noted: measles, 106; scarlet fever, 46; influenza, 6; cancer, 34; organic heart disease, 362; bronchopneumonia, 327; diarrheal diseases under five years of age, 468; accidents other than sunstroke, 47; homicide, 26; under five years of age, 51; sixty-five years and over, 147. The decrease in deaths from pulmonary tuberculosis, lobar pneumonia and kidney disease is encouraging, but, on the other hand, the very considerable increase in deaths from cardiac trouble is somewhat ominous. The large increase in infant mortality from diarrheal disease is somewhat difficult to understand, for the past summer was a comparatively cool one, while all the agencies which have of late years been employed for the saving of life among infants and young children were probably in more general operation than ever before. The increase in bronchopneumonia is sufficiently explained by the unusual prevalence of summer diarrhea, as the association of the two affections has long been recognized.

NOV. 9, 1907.

1. MEYER, W. *Kühn's Lung Suction Mask for the Hyperemic Treatment (Bier) of Pulmonary Tuberculosis.*
2. *MORTON, W. J. *Radium for the Treatment of Cancer and Lupus.*
3. COFFIN, L. A. *Intracranial Complications of Diseases of the Accessory Sinuses of the Nose.*
4. ROCKWELL, A. D. *Phototherapy in Neuritis.*

2. Morton reports 15 cases of carcinoma, sarcoma and lupus treated by radium. All the cases did well. Most were apparently cured, some after a period of years, although a few were inoperable from the ordinary surgical point of view. The writer believes that radium possesses distinct advantages over the x-ray, viz., greater accuracy of dosage, deeper, wider and quicker action, and the ability to utilize the cathode rays. The use of pure radium is an essential. As a routine he gives internally radio-active water, and also aqueous solution of fluorescin, esculin, or quinine to combine with the radium and produce fluorescence internally. [R. I. L.]

1. Ravenel has gathered a large amount of statistical and other evidence as to the various possible modes of entrance into the human body of the bacillus of tuberculosis. He first considers the alimentary tract in its different portions as a route of invasion. The tonsils are probably of importance in this connection. The frequency of infection by bacilli which enter through the intestinal mucous membrane is now believed to be great in consequence of recent work proving that the bacilli can readily gain entrance without producing lesions at the point of entrance. It is shown that the bacilli are then taken up by leukocytes and transported to mesenteric glands, or by the thoracic duct to the venous blood current. It is further shown that a considerable proportion of cases of tuberculosis in man, especially when the history points to intestinal infection, are due to bacilli of bovine type. Contact infections, by kissing, by the handling of contaminated articles, etc., and infection by droplets expelled during coughing and sneezing are also described, but greatest stress is laid upon the importance of recognizing the intestinal route of infection and the probable danger from milk of tuberculous cows.

2. Brewer reports 6 cases of abscess in the left lower quadrant of the abdomen, all of which probably, and 3 of which certainly, were due to perforation of acquired diverticula of the descending colon or of the sigmoid flexure. Minute diverticula, or herniæ of the mucous membrane through the muscular coats of the colon are recognized by pathologists as of not infrequent occurrence. It is believed that their importance as a cause of abscess formation and of peritonitis is not sufficiently well recognized.

3. Cabot and Bruce hold that it is important to supplement the current methods of heart examination by tests to determine the functional capacity of the cardiovascular apparatus, the capacity of the heart for work. For this purpose they have tested several methods and have found them to be of value, especially a modification of Gräupner's method which they perform as follows: the patient is caused to perform a certain number of foot-pounds of work in one minute, by ascending a flight of stairs, the pulse-rate and systolic blood pressure being taken every two minutes. Normally, the pulse-rate which has risen at first has fallen again within four minutes or so; the blood pressure normally rises to a maximum reached six or eight minutes after the beginning of the test. In cases of weak heart the rise of blood pressure is delayed or in severe cases it may be absent.

4. The article of Crile and Lenhart shows by a brief review how unsatisfactory has been the treatment of gas poisoning by the various methods hitherto attempted. With this in mind the authors have treated animals poisoned by gas by blood transfusion as well as by other methods. Of the 6 animals treated by other methods all died; of the 10 animals treated by transfusion 7 lived.

5. Goodman argues with Schlesinger and Holst that the benzidin test is superior to the guaiac and aloin tests for blood in stomach contents, feces or urine. It is simple,

sharper and yet not too delicate to be practical. It is well, however, to confirm positive reactions by the guaiac or the aloin test. The benzidin test is performed as follows: a small portion of the feces solution, obtained by grinding up the feces with water, is poured into a test tube and boiled. While this is cooling a concentrated solution of benzidin is made by dissolving as much benzidin (Merck, puriss.) as is contained in a very small spoon spatula, in 3 to 5 cc. of glacial acetic acid. To 1 cc. of this are added 3 to 10 drops of boiled feces solution diluted with equal parts of water. To the shaken mixture 1 to 3 cc. of 3% H_2O_2 are added. In the presence of blood a deep green or blue color appears. A negative test is certain evidence of the absence of blood. In event of a positive reaction meat in the diet, or the presence of iron, KI, Cu or animal charcoal must be excluded.

7. Lerche mentions cases of diffuse dilatation of the esophagus without organic stricture of which Neumann in Germany has collected 70, but of which very few appear in American literature. He summarizes the results of previous articles bearing upon spasmodic stricture or cardiospasm, and reports a case of ten years' duration where this was present with diffuse dilatation of the esophagus above. The cardiac was dilated by a rubber bag attached to a stomach tube and distended with water under pressure controlled by a manometer. Within two weeks after treatment the patient was well. The dangers of such dilatation, the precautions to be taken and the apparatus used in it by various authors are fully described.

9. Hamilton believes that typhoid is of more frequent occurrence in middle and later life than is generally taught. He bases this belief upon an epidemic of 188 cases of which 27 or 14% were over fifty years of age. The clinical picture in these older persons was usually atypical. The prodromal stage was generally lengthened, the diurnal variation of temperature was greater, chills and sweats, intermittent pulse, cough and digestive disturbances were more common than is usual in typhoid. Mental symptoms were not prominent. Enlargement of the spleen and rose spots were often absent. The mortality in these 27 cases was 22%.

10. Thompson finds that in infantile atrophy the parathyroid glandules as well as the thymus, thyroid and adrenals show degenerative changes out of proportion to the wasting of fat and muscle. Little evidence, however, exists of any causal relation of these degenerations to the disease.

12. Calvert shows by drawings of anatomical preparations that the right pleural cavity nearly always extends inward over the front of the vertebral bodies, often to the left of the median line.

2. Immediate operation has been the axiomatic treatment for ruptured extra-uterine pregnancy. Simpson, with some others, believes this is not always advisable, and his experience with a hundred cases seems partly to justify the belief. He points out that a single hemorrhage from a tube, just as from the stomach, intestines, lungs or uterus, is seldom fatal, and by treatment with morphine and absolute quiet its recurrence can often be prevented till the patient has recovered from the primary shock, under judicious stimulation. In desperate cases, he thinks the risk of such delay is less than that of immediate operation which, however, is still always indicated when the patient is not too profoundly reduced and proper facilities are at hand.

3. In cancer of the cervix, lymphatic metastasis in tube or ovary is extremely rare. Taussig reports a case where it occurred apparently through the lymph channels of adhesions connecting the adnexa with the posterior cul-de-sac. Unless such adhesions exist, he therefore still advises leaving one ovary at hysterectomy for cancer of the cervix in women under forty.

5. Kanavel presents an elaborate study of the mechanics of chronic suppuration in the hand, undertaking, thereby, to show anatomic reasons for the sequence of involvement of the several parts and tissues. By injections with plaster of Paris he demonstrates the connective tissue spaces in which deep accumulations of pus may form, and the routes along which extension of infection is liable to occur. These data he applies and illustrates clinically, describing his incisions for the most adequate drainage of variously located infections, with a view to the best possible subsequent preservation of function. His paper is a valuable contribution to the intelligent treatment of the septic hand.

6. Halstead reports 3 cases of thyroid cancer: one died of secondary hemorrhage while the inoperable tumor was sloughing under Coley treatment; one recovered from operation but her further history is not given; one was well and without recurrence over a year after complete thyroidectomy. The liability of simple goiters to malignant degeneration leads him to urge early radical operation when a previously stationary thyroid tumor begins to increase in size.

10. Sinclair sketches the history of the treatment of puerperal sepsis, commenting on inefficient or injurious measures and describing his own method, which is essentially thorough curettage and copious irrigation and swabbing with weak corrosive sublimate, followed by a light gauze pack for twenty-four hours. This procedure is usually sufficient; but he repeats it, several times if indicated. He uses antistreptococcus serum as a valuable adjunct. The distinction between sapremia and septicemia he believes clinically unnecessary, since both are treated alike and priceless time may be lost waiting for a differential diagnosis. In the event of general peritonitis he advocates laparotomy and posterior colpotomy, with profuse, through and through irrigation. The burden of his plea is for promptness of action, recognizing, nevertheless, that the best treatment of obstetric infections is their prevention by the practice of scrupulous surgical asepsis.

2. Berry gives an analysis of 274 cases of removal of goiter by operation, which brings the total number of cases which he has done up to 400. There were 274 operations in 268 patients; 32 were males, 236 females. Of the various reasons for operation dyspnea was the chief in 177 cases, deformity in 31 cases, and discomfort or deformity in 47 cases and dysphagia in only 1 case. In 203 cases the goiter was encapsulated, in 71 cases it was not. One hundred and six of the encapsulated goiters were solid adenoma, 7 of the non-encapsulated were malignant; the cases of pure cyst were extremely rare; there were 7 non-malignant intra-thoracic goiters. As to the nature of the operation, in 209 cases he enucleated the goiter, with one death; in the remaining cases extirpation was done. Out of the 274 cases there were 6 deaths. He used a curved transverse incision in most instances, oblique incisions in a few. Neither myxedema nor tetany occurred in any case.

7. Hutchinson describes a case of diverticulum of the bladder in a femoral hernia and concludes that this condition is not at all uncommon in femoral or inguinal herniæ, especially in elderly subjects, and that in some cases it is almost impossible to avoid cutting open the bladder. In a case where the surgeon suspects that condition during operation the diagnosis may be confirmed by injecting water into the bladder through a catheter.

13. *DEAN, G., HOUSTON, T., RANKIN, J. C., RITCHIE, L. C. P., AND BUXTON, B. H. *Discussion on Phagocytosis.*

2. Murray gives results of 200 consecutive post-mortem examinations where there was no history or evidence of hernia; he found a potential hernia sac in 47. In these 47 bodies, 68 diverticula were present. Of the diverticula 13 were inguinal, 52 femoral and 3 umbilical. In 16 cases more than one diverticulum was present. The article consists chiefly of an argument supporting his theory of the congenital origin of hernia. He believes that circumstantial evidence in favor of the saccular theory of inguinal, femoral and umbilical hernia is so strong, so convincing, that he has every confidence in obtaining a verdict in favor of this theory from the general body of the profession.

5. McGavin demonstrates his method of using silver wire filigrees in the cure of herniæ usually considered inoperable. Such cases include those of repeated recurrence after operations for the "radical cure" of hernia; certain very large hernia; those in which there is a chronic condition tending to constantly repeated increase of intra-abdominal tension, such as chronic bronchitis, asthma, etc.; those cases in which the hernia is the direct result of loss of some portion of the abdominal wall, in consequence of accident or the operative removal of tumors; and lastly, those in patients beyond the age at which it is reasonable to hope for a cure by the ordinary methods. He discusses the use of perforated metal plates, woven wire gridirons and their disadvantages, and describes in detail his method of making the silver filigree which he uses. Asepsis is of paramount importance. The preparation of the skin before operation must be very thorough. The filigree should be placed for five or ten minutes in sufficient ether to cover it, as only in this way can the grease conveyed to it by the workman's hands be removed. From this it should be lifted by sterilized forceps and placed in actively-boiling soda solution till required, when it is lifted straight from the sterilizer into the wound. He closes the wound by means of Michel's clips. There is no drainage used in any cases. He places the filigree between the rectus muscle and its posterior sheath. Absorption of the wire is impossible and fracture is rare. His results have been eminently satisfactory.

13. Dean and others contribute articles bearing on the general question of phagocytosis. Dean's article is a consideration of Metchnikoff's work on this subject and the investigations following this leading up to Wright's work on the opsonic index. Houston and Rankin give a paper on the opsonic and agglutinative power of blood-serum in cerebrospinal fever, based on work during the epidemic which recently occurred in Belfast. Ritchie describes a method of recognizing the presence of specific substances in blood serum influencing phagocytosis, and its diagnostic applications. Buxton discusses absorption from the peritoneal cavity. These papers and the discussion which follows are of great interest, especially to those engaged in work on the opsonic index and its relation to medicine.

7. WEDERHAKE, K. *The Paraffin Prothesis.*
8. WUNSCH, M. *Apparatus for Scoliosis.*

1. Freund believes that the pernicious vomiting of pregnancy is due to an increased excitability owing to the action of toxins, plus a predisposition. The latter results from displacements of the stomach, chlorosis or anemia, nervous or hysterical conditions, or lesions in the nasopharynx. In 100 pregnant women, he found 66% had hypertrophy and swelling of the turbinate bones; this sets up reflex nausea, which is relieved when nasal conditions are cleared up. Constipation, traction of misplaced organs, catarrhs, erosions, ulcers, over-distention of the uterus are also causes. Prophylaxis is of extreme importance. Nervous or hysterical women should be given a course of suggestion as soon as pregnant, and care exercised not to exaggerate the ordinary symptoms. Relieve all reflex causes. Psychic and dietetic measures are the most important, remembering that it is more important to convince the patient that her stomach will digest a

small amount of food than to feed her copiously. In one case the author succeeded in stopping the vomiting by simulating artificial abortion, and he cites other cases cured by psychic means.

2. Bandler and Kreibich describe observations made on adults to determine the effectiveness of Pirquet's method of cutaneous inoculation with tuberculin. Pirquet's direction for children was to use old tuberculin diluted four times, but as the authors were dealing with adults they employed the reagent in full strength. The inoculation was made by applying 2 to 3 drops of tuberculin to the skin of the arm or back, scarifying with a lancet, and then scarifying in another place without the introduction of tuberculin as a control. Out of 37 cases in which no manifestation of tuberculosis existed, 15 gave no reaction at all at the first inoculation. On repetition of the test 2 cases showed a weak reaction. Of the remaining 22 cases, 10 gave a weak or indeterminate reaction, and the other 12 gave a distinctly positive result, shown in the form of redness and swelling at the site of inoculation. Another series of patients comprised individuals suffering from local cutaneous tuberculosis: out of 26 such cases, 22 gave positive results; the other four were cases of advanced miliary tuberculosis which also did not give any reaction to the injection of tuberculin. The failure of such patients to react to tuberculin has already been pointed out by several observers. The microscopic structure of the lesions produced at the site of the inoculation is also described.

3. Nagelschmidt recommends the use of local tuberculin inoculation in the treatment of lupus where the Finsen rays are not accessible, especially for isolated foci, also as a means of differentiating the tubercular skin affections. It has the disadvantage of leaving scars from the ulceration it produces.

6. Papaïoannou says that echinococcus is not at all uncommon in Greece, owing to the fact that the peasants and shepherds live in close association with their dogs. The wells and springs are also sources of infection. According to the statistics gathered by the author, 72% of echinococcus cases in Greece affect the liver, 3.4% the spleen, 2.5% the kidney, 7.7% the peritoneum, 4.7% the lungs, 1.2% the breast, .8% the orbit, 1.2% the bones, 4.7% the muscles, .4% the thyroid, and 4% the broad ligament. He describes several cases of the disease, particularly one in which the optic nerve was the seat of the cyst formation. The patient was a boy of twelve, who six years previously had developed pain in the right eye, which for a time was the seat of inflammatory conditions. Vision failed rapidly and disappeared completely at the end of one month. On coming under the author's observation there was pronounced exophthalmos and pain had recommenced. The diagnosis of new growth was made, but while evacuating the orbital contents, the cyst burst and its true nature became apparent. [L. G. M.]

3. Schenk and Scheib have examined a large number of laparotomy wounds, to find out in what per cent of the cases an absolutely bacteria-free operation is possible. Under the ordinary asepsis, as used in their wards, in 38 cases before the operation, the wound was sterile in 25 cases, in 13 bacteria were present. (Staphylococcus albus.) After the operation was completed and the fasciæ sewn up, cultures from the wound showed bacteria in all cases; once a bacillus, in 25 cases staphylococcus albus, in 4 cases a large diplococcus, and in 7 cases a mixed infection. Observation of the course in these cases showed that those cases in which bacteria were present in the wound were not always the ones which ran a post-operative temperature. A series of 45 cases was then examined, in which a much more careful aseptic technic was employed; the wound was found sterile in 23 cases before operation. After the operation the wound was sterile in 10 cases only. The post-operative course was normal in all cases in which streptococci were not found. The authors conclude that even under the most rigid asepsis, an absolutely sterile operation field is impossible.

6. Like all other substances prepared from the organs of animals, suprarenal extract is uncertain in its action, never of the same strength, and does not keep well. There are now three preparations which are chemical imitations of the suprarenal extract: (1) arterenin (dioxyphenylethanol-amin, (2) homorenon (ethylamino-aceto-pyrocatechin), and (3) synthetic suprarenin (hydrochloric acid-dioxy-phenylethanol-methylamin. Hoffmann has tried these preparations, especially the synthetic suprarenin, and finds that in local anesthesia in combination with novocain a perfect anesthesia is produced, with a much longer and more complete anemia of the operation field. The toxic action is no more than that of the old suprarenin, and it can be used with greater precision owing to its constancy, its chemical purity, and the fact that it can be sterilized. The author considers the use of this preparation a step in advance in local anesthesia. [R. D.]

3. Engel discusses the embryonal blood cells and their mode of formation, and points out that in certain blood diseases there is a return to the earlier type. In the cells of certain malignant tumors, lymphomata and carcinomata, the type of cell suggests the body cells as seen in the embryo. It has been found, of late, that injections of the tissues of mouse embryos retarded the formation or further growth of carcinoma in adult mice. This seems to suggest that malignant tumors are an abnormal return to the embryonic type, and opens a new path for therapeutic researches.

4. Manasse reports a case of a young man who complained of pain in the left side and much disturbance of digestion, associated with rapid loss of weight. When seen a large, smooth, somewhat fluctuant tumor in the epigastrium and left flank was found. The stomach was pushed up, the colon displaced downwards. The appearance was that of a pancreatic cyst, and no urinary symptoms were apparent. During the inflation of the stomach the patient suddenly voided a large amount of urine containing pus, with consequent diminution in the size of the tumor. The diagnosis of hydronephrosis was then made. At operation the left kidney was found to be in normal position and of normal size. The pelvis was, however, enormously distended. The ureter arose at the highest point of the pelvis and ran over the front of the kidney instead of behind it; a very rare anomaly. [R. D.]

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING DEC. 7, 1907.

C. F. STOKES, surgeon. Detached from command of the Naval Hospital, San Juan, P. R., and ordered to report to the surgeon-general of the Navy at the Navy Department for special temporary duty.

H. L. LANGNECKER, A. J. TOULON, D. G. SUTTON and E. W. BROWN, assistant surgeons. Appointed assistant surgeons from Nov. 29, 1907.

W. D. OWENS, passed assistant surgeon. Commissioned passed assistant surgeon from May 17, 1907.

W. A. ANGWIN, passed assistant surgeon. Commissioned passed assistant surgeon from June 2, 1907.

W. G. FARWELL, passed assistant surgeon. Commissioned passed assistant surgeon from June 28, 1907.

C. H. BARBER, surgeon. Orders of Nov. 11 modified; ordered to the Naval Hospital, Boston, Mass.

E. S. BOGERT, Jr., surgeon. Detached from the "Milwaukee" and ordered to the "Pennsylvania."

J. M. BRISTER, passed assistant surgeon. Detached from the "Pennsylvania" and ordered to the "Milwaukee."

F. M. MINSON, passed assistant surgeon. Detached from the "Philadelphia" and ordered to the Asiatic Station, sailing from San Francisco, Cal., about Jan. 6.

J. L. BELKNAP, assistant surgeon. Ordered to the Naval Hospital, Boston, Mass., revoked; ordered to continue duty on board the "Wabash."

W. P. SCHALLER, assistant surgeon. Detached from the "Brooklyn" and ordered to the "Pennsylvania."

G. C. THOMAS, acting assistant surgeon. Ordered to the Naval Hospital, Philadelphia, Pa.

H. G. BEYER, medical inspector. Ordered to report at the Navy Department to the surgeon-general of the Navy for special temporary duty.

E. A. VICKERY, assistant surgeon. Detached from duty at the Naval Hospital, Boston, Mass., Dec. 12, and ordered to Washington, D. C., Dec. 16, for examination for promotion and thence to duty at the Naval Hospital, Annapolis, Md.

D. G. SUTTON, assistant surgeon. Ordered to duty at the Naval Hospital, Newport, R. I.

J. MCGUIGAN, pharmacist. Detached from the Naval Hospital, Port Royal, S. C., and ordered to Washington, D. C., Dec. 16, for examination for retirement and then home to wait orders.

SOCIETY NOTICES.

INDUSTRIAL EDUCATION. — The Commission on Industrial Education of the Commonwealth of Massachusetts, acting under Section 6 of Chapter 505 of the Acts of 1906, will give a public hearing in Room 240, State House, Thursday, Dec. 19, 1907, at 7.30 P.M., to all persons interested in the question of the establishment by the state of one or more technical schools or industrial colleges, providing for a three or four years' course for extended training in the working principles of the larger industries of the Commonwealth.

TREASURY DEPARTMENT, BUREAU OF PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE. — A board of commissioned medical officers will be convened to meet at the Bureau of Public Health and Marine-Hospital Service, 3 B Street, S.E., Washington, D. C., Monday, Jan. 20, 1908, at 10 o'clock A.M., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine-Hospital Service.

Candidates must be between twenty-two and thirty years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character.

The following is the usual order of the examinations: 1, physical; 2, oral; 3, written; 4, clinical.

For further information, or for invitation to appear before the Board of Examiners, address Surgeon-General, Public Health and Marine-Hospital Service, Washington, D. C.

A PROPOSED NEW ENGLAND PEDIATRIC SOCIETY. — The Visiting Staff of the Boston Floating Hospital request all those interested in the formation of a New England Pediatric Society to meet at the Boston Medical Library, 8, The Fenway, Saturday, Jan. 4, 1908, at 8.15 P.M. It is hoped that this movement will excite general interest and that the attendance at the meeting will not be limited to those working along this special line.

JOHN LOVETT MORSE, *Chairman.*
WILLIAM E. FAY.
ARTHUR WILLARD FAIRBANKS.
CHARLES W. TOWNSEND.
HENRY I. BOWDITCH, *Secretary.*

RECENT DEATH.

DR. ISIDOR PIERCE OBERNDORFER, of New York, died from appendicitis, in which an operation failed to avert the fatal issue, on Dec. 1. He was graduated from the College of Physicians and Surgeons, New York, in 1874, and afterwards took a two-years post-graduate course of study in Leipzic University, Germany. At first engaging in general practice, he gradually devoted his attention more particularly to the treatment of diseases of the skin, and for many years he had been attending dermatologist to the German Dispensary.

A SERIES OF NINETY-ONE CONSECUTIVE BLOOD CULTURES.

BY LAWRENCE J. RHEA, M.D.,
First Assistant in Pathology, the Boston City Hospital,
AND
ARTHUR B. EMMONS, 2D, M.D.,
Senior Pathological Interne, the Boston City Hospital.
(From the Pathological Laboratory of the Boston City Hospital.)

THE following blood cultures were taken during the last three years as a part of the routine of the Pathological Department of the Boston City Hospital. They were made for the most part at the request of the visiting staff of the various services of that hospital. Consequently, we have had to deal with a large variety of diseases, both bacterial and non-bacterial in origin.[1]

The greater number of cultures was made on cases in which the clinical diagnosis was doubtful. In some instances confusing symptoms or signs, or evidence of intercurrent infection in known diseases, were the reasons for requesting a blood culture.

The clinical importance of blood cultures as an aid to diagnosis is demonstrated in several of the cases in this series. A general septicemia may present a classical picture or may be very confusing. It is in this latter group of cases that blood cultures will be of great aid to the clinician. In some diseases, as typhoid fever, a positive diagnosis can be made in a large per cent of cases some time before the Widal reaction is present or the clinical picture justifies a positive diagnosis.

In our work the following *technic* was used:

The flexor surface of the elbow was scrubbed with soap and water, washed in 70% alcohol, and a sterile dressing applied.

In cleansing the hands of the operator, soap, water and alcohol were used. An ordinary anti-toxin syringe was found to be the most serviceable for removing the blood. Care was taken to have sharp needles which had been tested before the culture was made, to be sure they were patent. Twenty centimeters of blood were removed, generally from the median cephalic vein.

The media employed as routine have been plain and dextrose agar, plain bouillon in flasks, litmus milk in flasks and serum waters. In cases where the clinical symptoms suggested some particular infecting organism, special media were used.

We feel sure, from our experience, that more blood cultures will be positive if the media used in each case are those most suitable to the growth of the supposed infecting organism.

All the media were inoculated at the bedside. The amount of blood added to each portion of medium varied. Where the symptoms suggested infection due to the colon group, a small amount of blood was added to a large amount of medium. In all cases a small sterile test tube was filled with blood and kept on ice for agglutination tests.

Anaërobic cultures were made only in cases where the bacillus aërogenes capsulatus was found in local lesions.

As routine, but one blood culture was taken from each case, but in some instances several were made. In a certain number of cases positive findings were obtained only after two or more attempts; in other cases, organisms were repeatedly recovered from the circulating blood. In this latter group of cases each successive blood culture showed the same organism as was recovered from the first.

Repeated blood cultures are of especial importance in cases where the common skin cocci have been obtained from the blood cultures in sufficient numbers to suggest a septicemia caused by these organisms. Such a case can hardly be reported as positive, unless the same organism has been present in at least two cultures taken from the blood at different times, or post-mortem findings show lesions unmistakenly produced by these organisms.

In the identification of organisms sub-cultures were made. The growth on the media used at the time a blood culture is made may be very suggestive, but in many cases it is not sufficiently conclusive to make a positive identification of an organism.

We used the inulin test in the differentiation of the pneumococci and streptococci. Those cocci in pairs or chains with cultural characteristics resembling streptococci, which showed no capsule and did not split inulin bouillon we called streptococci. If such an organism showed a capsule or split inulin bouillon, we called it pneumococcus. The staining of capsules of pneumococci grown on artificial media was not very satisfactory.

Cocci which grew in groups were planted on various media and their cultural characteristics studied. In all of these cases the cultures were grown in the thermostat, usually over night, and later at room temperature, in order to increase any pigment formation. Welch [2] has emphasized the importance of this point.

It is the custom of the Pathological Laboratory of the Boston City Hospital to report a culture negative only when the inoculated medium shows no growth after at least seventy-two hours incubation in the thermostat at 37° C. This prevents overlooking organisms which grow slowly. Even a longer time is necessary for some organisms, such as the tubercle bacilli.

After twelve hours all the inoculated media are examined. Those which show growth are studied. All colonies that have developed on the plates are surrounded by a pencil mark made upon the bottom of the plate. At the end of another twelve hours in the thermostat all new colonies are enclosed within a square made in like manner upon the bottom of the plate. This enables one to keep separate, colonies which have developed early from those which have developed

Bertelsmann: Allegemeineninfektion bei chirurgischen Krankheiten. Deut. Zeitschr. für Chir., 1904, vol. 72, p. 209.
Libman, E., in the Johns Hopkins Hospital Bulletin, 1906, vol. xvii, p. 215, has covered the literature bearing on special features illustrated in his 700 to 750 blood cultures.

[2] Am. Jour. Med. Sc., vol. cii, 1891, p. 439.

late. Such a procedure is especially useful in cases where two or more organisms are present in the circulating blood.

The contaminator most frequently met with was the staphylococcus epidermidis albus. While it is difficult to prevent an occasional contamination with a colony of this organism, thorough sterilization of the patient's skin lowers its frequency. The cases in which we found it oftenest were those where some difficulty had been met with in entering the vein, necessitating more or less manipulation of the seat of puncture. In our cases all contaminating organisms were thoroughly worked out.

But one culture showed more than one organism present in the circulating blood — a case of septicemia following an abortion. From this case the staphylococcus pyogenes aureus and staphylococcus pyogenes albus were isolated.

In several cases one organism was isolated from the blood and one or more different pathogenic organisms recovered from local lesions in the same case. These associated organisms were found in local lesions present at the time of the culture from the blood or developed later in the course of the disease.

Only a small per cent of the fatal cases came to autopsy. Later in this paper we compare the ante-mortem and post-mortem findings.

Of the 91 blood cultures taken, 36 were positive and 55 negative.

The following organisms were recovered[3]: streptococcus pyogenes in 13 cases; pneumococcus in 6 cases; staphylococcus pyogenes aureus in 7 cases; gonococcus in 2 cases; staphylococcus pyogenes albus in 2 cases; bacillus mallei in 1 case; bacillus mucosus capsulatus in 1 case; bacillus anthracis in 1 case; bacillus paratyphosus in 1 case; bacillus aërogenes capsulatus in 1 case; staphylococcus citreus in 1 case; bacillus typhosus in 1 case.[4]

Of the 13 positive cultures of streptococcus pyogenes, 5 were recovered from patients on the surgical services, 6 from patients on the medical services, and two from patients on the gynecological service. Eight patients died; 5 recovered. Five deaths and 1 recovery occurred in cases from the medical services; 3 deaths and 2 recoveries in the cases from the surgical services. Both of the patients on the gynecological service recovered.

The surgical cases included:

1. One compound fracture; death; no autopsy.

2. Osteomyelitis with multiple abscesses; recovery.

3. Septic arm (cause unknown) with later involvement of one knee. On the day of the blood culture an evacuated abscess showed an organism which morphologically and culturally strongly resembled the pneumococcus. Recovery.

4. Traumatic amputation of the leg; death; no autopsy.

5. Multiple acute osteomyelitis with acetonuria; death; no autopsy.

The case of multiple acute osteomyelitis with acetonuria is interesting from the presence of the staphylococcus pyogenes aureus in two of the infected bones and the streptococcus pyogenes in another. This patient, a girl twelve years old, entered the third surgical service April 4, 1904. For a week she had complained of pain in her right knee and had had some fever. The lower end of the right femur was operated upon for acute osteomyelitis on April 6. A pure culture of staphylococcus pyogenes aureus was obtained from the pus. The upper end of the left humerus was trephined for acute osteomyelitis on April 8. The pus showed a pure culture of staphylococcus pyogenes aureus. The left tibia became involved, and was opened on April 13. A mixed culture of streptococcus pyogenes and staphylococcus pyogenes albus was obtained. Two days after this, a blood culture showed a pure growth of streptococcus pyogenes. In the latter part of the patient's illness, acetone appeared in the urine. Two days later diacetic acid was present. These substances gradually increased in amount, varying somewhat from day to day, until death. During the last three days of life there was marked vomiting.

Two surgical patients recovered. One had multiple subcutaneous abscesses with osteomyelitis. This patient was operated upon six times during a period of eighteen days. From an abscess opened a few days previous to the blood culture, the staphylococcus pyogenes albus was recovered. The second case had multiple subcutaneous abscesses with a swollen and painful knee. This patient was operated upon four times during an illness of seventy-one days. From an abscess opened ten days before the blood culture was taken, a pure culture of an organism which morphologically and culturally corresponded to the pneumococcus was obtained. Five days after the blood culture, a local lesion over the shoulder showed streptococcus pyogenes.

There were 6 positive cases of streptococcus pyogenes from the medical services. Five of these died and one recovered.

There were 2 autopsies in this group of cases. In both instances the clinical diagnosis and blood culture finding were confirmed.

1. One case of tonsilitis and pharyngitis, with acute involvement of the glands of the neck. Recovery.

2. Four cases of malignant endocarditis. All died.

3. One case of septicemia without a clinically demonstrable point of entrance. Death.

From the gynecological service there were 2 positive cultures of streptococcus. Both recovered. One followed an abortion. In this case the streptococcus pyogenes was recovered in pure culture from the uterus.

The staphylococcus pyogenes aureus was recovered from 7 cases, six times in pure culture and once associated with the staphylococcus pyogenes albus. Six of these cases died. One

[3] Five of the blood cultures included in this list have been reported by Duval and Lewis, Jour. of Med. Research, vol. xiii, p. 513.

[4] We have done but few blood cultures on patients in whom a clinical diagnosis of typhoid fever has been made. Several of these later proved not to be typhoid fever.

upon whom a culture was taken a few days ago is still alive.

1. One case with septic wound of the knee, followed by acute inflammation of a joint of the forefinger. Pneumonia developed.

2. One case with severe pharyngitis followed by signs and symptoms of septicemia. There was marked jaundice.

3. One case of malignant endocarditis secondary to acute suppurative otitis media.

4. One case with meningeal symptoms developing three weeks after a blow on the head. From a post-mortem lumbar puncture, the staphylococcus pyogenes aureus and the pneumococcus were recovered.

5. One case of septicemia following an abortion.

The staphylococcus pyogenes aureus as a cause of post-partum septicemia is not very common.

6. One case of empyema, secondary to a lung abscess. A pneumonia and signs and symptoms of a brain abscess developed three days before death.

7. One case upon whom a clinical diagnosis of perinephritic abscess was made. The right testicle became involved, was opened and from the pus a pure culture of the staphylococcus pyogenes aureus was obtained. The blood culture was done the day following this operation. Focal lesions of the testicles in septicemia are uncommon. This patient is still in the hospital. He shows some improvement.

In the case of tonsilitis followed by marked jaundice, an autopsy was made. There were focal abscesses of the lung, spleen and liver and a few small subcutaneous collections of pus.

The gonococcus was isolated from 2 cases. Both recovered. In one there was a clinical diagnosis of gonorrheal arthritis; in the other of malignant endocarditis. Both patients showed acute gonorrheal urethral discharge.

The pneumococcus was recovered six times. In all these cases a clinical diagnosis of lobar pneumonia had been made. One was complicated by empyema.

Five of the cases from which the pneumococcus was recovered from the circulating blood died; one recovered.

The patient that recovered after a pneumococcic septicemia, a male, aged twenty-six years, showed a typical course of lobar pneumonia with crisis and uneventful convalescence. The blood culture was taken on the day of the crisis. It would scarcely seem possible that the disappearance of the organisms from the circulating blood could have been as rapid as the crisis. In such a case, it would have been interesting to have taken cultures on several successive days following the crisis, to determine how long the organisms remained in the circulating blood, after the temperature became normal. That pathogenic organisms can exist in the circulating blood, even in great numbers, without causing symptoms, is well illustrated in one of our cases, given later in detail, the one from which the bacillus mucosus capsulatus was recovered.

Two autopsies were made on this group of cases. In both there was extensive solidification of the lungs. In one case the pneumococcus was recovered from the lungs, liver, spleen and kidney. There is no record of cultures having been taken in the other case.

The staphylococcus pyogenes albus was recovered from 2 cases; once in pure culture and once associated with the staphylococcus pyogenes aureus. Both cases were fatal.

The case from which the pure culture was recovered had had acute articular rheumatism several times. We are unable to determine definitely the relation of the time of death to the time when this blood culture was taken, and are unwilling to consider this a positive finding. A positive culture obtained a few hours before death might represent agonal invasion.

Seven different organisms have been found but once:

Bacillus mallei, bacillus mucosus capsulatus, bacillus anthracis, bacillus paratyphosus, staphylococcus citreus, bacillus aërogenes capsulatus, bacillus typhosus.

The case from which the bacillus mallei was recovered gave the following history: Male, age, forty-nine years, hostler. Had been in contact with glandered horses. Present illness: Has been sick several days; chills, sweats and pain in chest.

Physical examination. — Signs of pneumonia. Skin shows an eruption consisting of macules, papules, vesicles and pustules, marked over face, chest and limbs, especially about knees and elbows. The right little finger and left small toe are swollen, and of a dark red color. The joints particularly seem affected. There are deep abscesses, showing little reaction, over the right thigh and anterior surface of both forearms. The patient's condition became progressively worse and death occurred five days after admission.

AUTOPSY FINDINGS.

Resolving pneumonia (right). Fibrinous pleurisy (right). Abscess of lung (right). Multiple subcutaneous abscesses. Pustular and papular skin lesions. Acute hemorrhagic leptomeningitis (right). Acute cellulitis of the scalp.

Cultures from abscess of lung, beneath scalp, and the abscesses over the arms and thigh showed the bacillus mallei mixed with the streptococcus pyogenes and the staphylococcus pyogenes aureus.

The bacillus mucosus capsulatus was isolated from a male, aged thirty-seven years, cigar maker.

Past history. — Unimportant.

Present illness. — For two weeks he has had severe general body pain with tendency to localization in joints. Right leg has been especially painful for two days.

Physical examination. — On entrance the right leg was markedly swollen and cyanotic. Pitted on pressure. There was a diffuse purpuric mottling over whole leg without any sharp lines of demarcation. Forty-eight hours later condition

extended to axilla on that side. After five days local symptoms on right side gradually decreased. At same time the left leg began to swell, repeating completely the changes gone through on the right. Recovery was gradual and uninterrupted. The patient was discharged after five weeks.

On three occasions a blood culture showed the bacillus mucosus capsulatus in pure culture and in enormous numbers. At each time the number had increased. The last culture was taken on the day of discharge, five weeks after admission and four weeks since the previous blood culture.

The bacillus anthracis was isolated from a male; freight handler working on imported hides. He cut his chin on Nov. 13, 1904, while shaving. By Nov. 16, 1904, a small crust had formed at the site of the wound. This patient showed the typical pustule with corresponding general symptoms. A blood culture taken at the time of operation, when the pustule was excised, showed a pure growth of bacillus anthracis. After three weeks the patient was discharged well.

The patient from whom the bacillus paratyphosus was recovered gave the following history: Woman, single. Age, twenty-three years. Entered the gynecological service, June 25, 1904. For the past year she had complained of pelvic pains. Recently pelvic sinuses developed.

Present illness. — Twelve days before entrance, at her regular catamenia, she began to have pain in her left lower abdominal quadrant. This has continued with an occasional chill, some vomiting and fever.

Physical examination. — Negative except for tenderness in lower left abdominal quadrant and pelvic condition.

The pelvic condition was treated and improved. The temperature remained high with morning and evening variations. The Widal reaction was negative. No rose spots.

Fifteen days after entrance a blood culture showed a pure growth of the bacillus paratyphosus. This organism was completely agglutinated by the patient's blood, in dilutions as high as 1 in 500, with slight clumping up to 1 to 1,000. The bacillus typhosus was not agglutinated. Thirty days after entrance, this patient was discharged relieved.

The staphylococcus citreus was recovered from a gynecological patient who had acute pelvic inflammation, with foul discharge from the vagina. Vaginal section showed a pelvic abscess. She ran a septic temperature and died twenty-five days after the blood culture was taken.

An autopsy showed chronic salpingitis, abscess of ovary, pelvic peritonitis.

Cultures from the heart's blood were sterile.

The bacillus aërogenes capsulatus was isolated from the circulating blood of a woman who entered the gynecological service, Aug. 21, 1906. She gave the following history: Age, thirty-four years.

Past history. — Unimportant.

Present illness. — Two days previous to entrance she had a self-induced abortion.

Physical examination. — An obese, well developed female. Some general dusky hue of the skin. Restless. Temperature 105°, pulse 110. A small mass of placental remains was removed from the vagina.

The general bluish discoloration rapidly increased in intensity, becoming very prominent. Subcutaneous emphysema developed in the groins and inner side of the thighs. The patient rapidly failed and died twenty-four hours after admission.

Smears made at the time of entrance, from a swab from the uterine cavity, showed organisms which morphologically corresponded with the bacillus aërogenes capsulatus, along with a few cocci and a few Gram-negative bacilli. From cultures made from this same swab the bacillus aërogenes capsulatus was recovered.

A blood culture was taken eighteen hours before death. Anaërobic cultures were made and in addition a few drops of fresh blood were injected into the ear vein of a rabbit. The rabbit was killed in two minutes and placed in the thermostat at 37° C. for eight hours. From both sources the bacillus aërogenes capsulatus was recovered in pure culture.

An autopsy on this patient showed the typical lesions caused by bacillus aërogenes capsulatus, foamy liver, etc. This organism was recovered from the liver and heart's blood.

The negative blood cultures cover a long list of clinical diagnoses. Some of these clinical diagnoses proved to be incorrect, and some remained doubtful. Some blood cultures were taken from cases in which, later, the symptoms were proved to be of non-bacterial origin. In a certain number of cases, clinical observation has left little doubt that we were dealing with a septicemia; a few cases strongly suggested infection due to a particular organism. Negative blood cultures on cases where the symptoms strongly suggested a septicemia might have been due to any one of three causes: improper media were used; the culture was not taken during the acute stage of the disease; or there were too few organisms in the circulating blood.

In such a group of cases, only repeated blood cultures or post-mortem examinations would do much toward clearing them up.

Nineteen of the 55 patients showing negative cultures died. Autopsies were made on 2 of them; one a case of tetanus, the other a case of septicemia following a pelvic abscess.

SUMMARY AND CONCLUSIONS.

In this list of 91 blood cultures, 55 were negative, 36 positive. Forty-three patients died; 47 patients recovered; one is still in the hospital. Of those who died, 24 patients showed positive cultures, 19 patients showed negative cultures. Eleven patients showing positive cultures recovered and 1 patient is still in the hospital, improving. Thirty-six cases showing negative cultures have recovered. Autopsies were made on 8 positive cases and on 2 negative cases. From 5 of the positive cases with autopsies the same organisms were recovered post-mortem as from

the blood culture. In 2 cases there is no record of post-mortem bacteriological examination.

In comparing organisms recovered post-mortem with those obtained during life, agonal and post-mortem invasion must be considered.

We wish to emphasize the importance of repeated blood cultures in cases which clinically suggest septicemia, although one or more cultures from the blood have shown no organism.

THE EFFECT OF FLORIDA CLIMATE UPON ACUTE AND CHRONIC DISEASE.*

BY F. FREMONT-SMITH, A.B., M.D., WASHINGTON, D. C.,
Assistant Professor of Pediatrics, George Washington University; Assistant Pedriatrist to the University Hospital; Attending Physician to the Foundling Hospital, Washington, D. C.

THE varieties of climate which the different parts of Florida offer during the winter months are surprisingly diverse in a locality so nearly approaching tropical conditions.

Until recent years the southern portion of the state has been practically unknown, northern and central Florida alone having been enjoyed as a winter resort.

The climate of the Northern Atlantic coast of Florida is represented by that of St. Augustine and Ormond. In the former the winters vary with successive seasons but there are many bright, beautiful and sunny days during the least salubrious months, January and February. This northern region, however, is subject to occasional passages of cold waves which, coming from the northwest, sweep over Texas and across the Gulf and point their central force towards this part of the state. In recent years attacks of cold and frost have been more severe than for many previous decades. During such attacks warm clothing is required and hotels are supplied with steam heat and comfortable accommodations. These waves of cold usually continue for three days, followed by fair, sunny weather. The climate of St. Augustine and Ormond is not dry, nor is that of Florida in any part. It is classified as of medium humidity. Both localities are surrounded by salt water, and fresh water is not to be found in their vicinity. Neither has suffered from malaria, and the drainage of the hotels and large boarding houses in both of these resorts is as perfect as science and careful engineering can make them.

St. Augustine stands upon a neck of land surrounded by the waters of the sea; to the eastward stretches the Atlantic; to the west rise high sand ridges covered with a growth of healthy pine. It is separated from the sea by a narrow island, many miles in length, forming its harbor.

St. Augustine has an ancient renown for healthfulness. Bernard Romans, in the "Natural History of East and West Florida," 1775, writes: "I do not think that on all the continents there is a more healthy spot." Wm. Darby, "History of Florida," 1821, says: "The remarkable healthfulness of the situation will render it the Montpellier, of the Atlantic Coast." James Grant Forbes, in "Sketches of Florida," 1821, adds: "Accounts from all quarters correspond in representing the capital (St. Augustine) as the Montpellier of North America, to which the healthy repair for refreshment, the invalid for health."

In "Observations upon the Floridas," by Chas. Vignoles, 1815, is written: "The undeviating salubrity of the St. Augustine climate is almost one continued spring."

In 1837, John Lee Williams, in "The Territory of Florida," says: "The situation is peculiarly serene, healthy and pleasant."

George R. Fairbanks, "History of St. Augustine," 1858, confirms these statements, *viz.*: "The Spanish settlement of St. Augustine has remained for nearly three hundred years where it was originally planted, and the health of its inhabitants has for this long period given it a deserved reputation for salubrity and exemption from disease," "a situation combining more local advantages for salubrity could hardly be imagined."

This history of remarkable healthfulness continued until the spring of 1902, when an outbreak of typhoid fever occurred, embracing but a very small proportion of the large number who visited the city that season, but all attacked were persons of prominence, and their names were widely spoken.

Of these cases, Dr. John S. Billings, who the same season made a thorough, official investigation, reports: "It is probable that two or three of them were not typhoid at all, that two of them were ill on the day of their arrival, which illness became well marked typhoid five days later and, therefore, was not contracted at St. Augustine, and that of all the cases at the above mentioned hotels [Ponce de Leon and Cordova and Alcazar] there were among the guests but three which it would seem must have been contracted during their stay in St. Augustine. The four servants affected with typhoid probably had the specific cause introduced into their bodies through contact with a fever case or cases or with soiled linen from such case."

"Every educated physician will understand from the above figures the extreme improbability that so few cases (13) scattered over a period of two months and giving a ratio of less than one to a thousand people exposed, could have been due to anything in the structure of the buildings, the general water supply or the food, milk or ice, and the detailed investigation of all these things makes it practically certain that no case of typhoid was due to any of them."

Later history has borne out the correctness of Dr. Billings's opinion; during subsequent winters in my own experience until 1898, and since that time in the experience of Dr. M. W. Seagears, rarely has a case of typhoid appeared at St. Augustine. This northern region of Florida has, however, suffered for short periods in recent years more than the southern part of the state, from mild influenza. This disease, which attacked Florida but lightly, during its earlier invasion of

*Read before the American Climatological Association, May 5, 1907.

this country, came during the winter of 1900 with the onset of cold northwestern waves, in an active form. It was delayed until early March and persisted for two weeks. It was not accompanied by serious complications, but was characteristically epidemic. Scarcely a season since has northern Florida been free from some definite signs of its presence.

The exanthemata, when imported, have in my experience run an extremely mild course. In May, 1893, a mild epidemic of scarlatina occurred among the resident people, after the winter visitors had departed, but it was so indefinite that it was with difficulty recognized. No children suffered complications, none were kept in bed, and it was not until desquamation defined the diagnosis that the physicians then remaining in the city were able to give a positive opinion.

March and April at St. Augustine are most perfect months; bright, sunny days, with temperature rising to 70° to 75° and without evening chill, are almost continuous. This agreeable condition is equally true of Ormond and Daytona, and the choice of winter location may be determined by the fancy and pleasure of the patient rather than by any large differences in climatic conditions.

Of the more tropical portions of Florida, Palm Beach and Miami are the representatives on the eastern coast; on the west or Gulf coast, and in the interior, numerous points of comfort with proper appointments for health, have developed.

Palm Beach is situated at the most eastern point on the Florida coast, is bathed by the waters of the Gulf Stream, and is free from contamination of fresh or brackish water. The vegetation, though rich and beautiful, is not dense. Both Palm Beach and Miami are usually below the frost line. In 1899 the temperature fell once at the former to 33°, in 1906 once to 25°, and in 1907 to 28°. This region feels the effects of waves of cold borne down from the northwest much more mildly and for shorter periods than the higher latitudes of the state, yet there are days in January and February when an overcoat is necessary and when hotels turn on the steam heat. During each season there are at least three or four cold waves, as shown in the accompanying tabulation, sufficiently severe to render warm clothing and careful protection of the delicate, imperative.

These attacks of cold break, usually, on the middle of the third day and the normally mild climatic conditions are restored the moment Boreas ceases his attack.

The prevailing winds in southern Florida are southeasterly, directly off the ocean, a gentle, steady breeze during the entire day and lasting through the night.

Decidedly the most favorable feature for the delicate is the absence of evening chill. With the setting of the sun comes no appreciable fall in temperature, and in this the climate has an advantage over southern California, the upper Nile and the Riviera.

Sparks, writing of the Riviera, says: "The chief drawback to the climate is the occasional occurrence of winds, cold from the northeast and east, very dry from the west and northwest, and of periodic droughts."

At Nice, San Remo and Mentone, it is the custom of physicians during the winter months to recommend both well and ill to remain indoors after 3 o'clock in the afternoon until the setting of the sun, in order to avoid the chill damp which rolls down the lofty mountains at whose base they lie.

The best test of a climate is the healthfulness of the employees of hotels and grounds. These are imported persons, they work hard and take plain food, their habits are careless and they are constantly out in the night air. If malarial infection were present, it should manifest itself first among these employees. Of more than a thousand under my care during each of six years, I can say that in only a single instance have I seen a chill from any cause, nor have I seen a case of dysentery in any of them for that period. Among guests I saw an annual average of one case of dysentery.

I saw in 1899 one case of malaria among guests, a Yale student in reduced health. Under the usual medication the symptom never recurred; he spent his days at golf and sailing, recovered health, vigor and strength, and gained 11 lb. during his six weeks' stay. In the winters of 1900–1904 my experience with employees was exactly similar, neither malaria nor dysentery manifested themselves in any form; among guests two cases of malaria occurred in persons bearing a history of infection, a chill in each, once, and not repeated. No case of dysentery was observed in this period.

Among a very large number of children spending a part or the whole of the winter at Palm Beach, I had little occasion for practice. They were all, barring minor complaints and one case of bronchopneumonia, in good health during these winters. One case of pneumonia and one of diphtheria were imported, ill on the day of arrival.

The climate and sanitation of Miami is similar to that of Palm Beach. The choice will depend upon social and economic reasons, rather than upon any considerable atmospheric differences which may exist.

In this connection, I may say one word of the Island of Nassau, easily reached from Miami. I can speak of it with favor because of the uniform verdict of many friends and patients who have had long experience there. Cold waves are scarcely noticed. Temperatures are more uniform than in any part of Florida; drainage and sanitation are perfect, and the inviting atmosphere of the place, its unique and peculiar native life, its attractive sailing grounds and its excellent hotel and boarding accommodations, render it charming to the tourist and health seeker. The objections for invalids, to which my attention has been called, are occasional rough voyages, rather persistent stiff breezes which blow across the island with a velocity greater than at any Florida resort and the glare from the white rock

used in the construction of buildings and road beds.

Throughout Florida acute digestive derangements occur rather frequently in recent arrivals, partly by reason of the radical change from winter to summer, made in the interval of twenty-four to forty-eight hours (unlike nature's birds of passage), producing a state equivalent to the spring lassitude or so-called biliousness of northern May and June; in part also on account of dietetic indiscretions incident to a hotel table. Persistent diarrheas, excepting occasionally with the very aged, I have rarely seen. Acute intestinal disturbances, as the season advances to the warmer days of March, are not uncommon. Repeated investigation of food and water supplies have convinced me that these are not the cause. Attacks of mild diarrhea supervene on hot waves, just as they appear in the New England mountains and along the Atlantic seacoast in latter summer and early autumn. Colitis attacks are extremely rare, vastly less so than on the Maine coast in early autumn.

In 1897, I made a report before this society on pneumonia in Florida, for a period of five years. Among about 400,000 white and colored inhabitants, the average annual number of deaths from pneumonia was 165.4 or .42 per 1,000 inhabitants. In the east coast counties, from St. Augustine southward, the mortality was 1 to each 3,576, or .27 per 1,000 inhabitants. That this remarkably low mortality from pneumonia in Florida must be credited to favorable local climate, is more readily appreciated when we reflect that the average mortality is 1.5 per 1,000 in northern and temperate latitudes of Europe and America; that Greece, Italy and Turkey suffer severely; that the disease is often epidemic in sub-tropical and tropical countries like the Sudan, the west coast of Africa, and the upper Nile, and that in the West Indies and South American countries the natives have a very heavy death-rate from this disease.

It is manifest from the foregoing that there is little fear of serious acute illness by winter residents of Florida.

The improving effects of Florida climate upon chronic disease is greater than that of sea level in summer at the north, by reason of almost continuous sunshine, absence of evening chill and the slighter diurnal temperature variations. Diseases of the circulatory and excretory systems find here specially favorable conditions, particularly those forms dependent upon arteriosclerosis, local or general. Cardiac excitement is relieved and arterial hypertension receives some reduction. I have not infrequently seen cases of albuminuria greatly benefited by prolonged residence in Florida, and occasionally incipient subjects have returned to perfectly normal conditions.

Functional nervous diseases, whether dependent upon presenile sclerosis of blood vessels or upon the stress and strain of modern life, are favorable subjects for this sedative climate. The stimulus to mental activity is removed, and persons even in perfect health note a decided soporific influence. Respiratory diseases, if catarrhal or delayed convalescent from pneumonia or bronchitis, as well as cases of tuberculosis in the inactive fibroid stage, can find no more advantageous winter home.

Acute stages of pulmonary tuberculosis do not receive, in my experience, the advantage which might be anticipated from the out-of-door treatment in this climate. I have in many instances known of great improvement or recovery in persons whom I have directed from Florida to the more invigorating climates of mountain regions or to southern California, other conditions remaining practically unchanged.

Gouty and rheumatic subjects, with incident neuralgias or neurites, have frequently and rapidly improved under my observation in this greatly eliminative atmosphere.

To what extent our families, sent to Florida, are exposed to acute and climatic diseases, twenty years of personal experience make it possible for me to state with reasonable accuracy. That this sub-tropical sea climate has also definite influence in delaying the progress of already established chronic disease, I cannot doubt, and in certain border-line cases, as in albuminuria, definite cures have been accomplished. The objections to winter residence in Florida, which should be noted, are hotel and boarding-house life and food, which can rarely be equal to home surroundings and table, absence of sustained diversion for such as do not take up golf or tennis, and who are indifferent to sailing and fishing. Sitting out of doors and wheel chair or carriage driving soon cease to be an amusement to the average restless American mind.

One other objection, which to a small proportion is an important one, is the relaxation, the so-called enervating effect of the climate. In some persons, well or ill, this becomes a positive torpidity, physical and mental, with painful languor and lassitude, simulating illness; to such the climate is not adapted and they should return to the bracing influence of northern chill.

The advantages of easy accessibility for residents of the eastern half of our continent, of freedom from the dangers of acute and climatic illness, as I have pointed out, and the toning down of the overworked and overwrought nerves of the average American, associated with its tendency to stimulate nature's restorative processes, are all that should be claimed for Florida's influence upon health and disease.

Climate of Palm Beach, Fla.

Temperature:[1]

A STUDY OF FIFTY-ONE CASES OF DEBILITY IN JEWISH PATIENTS.

FROM THE OUT-PATIENT DEPARTMENT, MASSACHUSETTS GENERAL HOSPITAL.

BY H. MORRISON,
Fourth-Year Student at the Harvard Medical School.

THE term "Hebraic debility" has been used for some time at the Massachusetts General Hospital to designate the condition of many of the Jewish patients coming to the clinics. These patients complain of "burning" and "sticking" pain, generally in the chest and epigastrium, but often all over the body. "*Es brennt mich*," "*es stecht mich*," and "*schmerzen überall*" are familiar expressions in their stories. The history of one of these patients has been summed up as follows: "She complains of backache and everything else." One of the physicians at the hospital was inclined to think that such symptoms were peculiar to Jews, that they were more than mere neurasthenic symptoms, and he suggested that I should study these patients by visiting them at their homes so as to get the details of their ailments and observe their modes of living.

MOST OF THESE PATIENTS ARE RECENT IMMIGRANTS. ALMOST ALL GET WELL.

I have studied 51 cases, confining myself to those in which the diagnosis of "Debility" or "Hebraic debility" had been made at the Massachusetts General Hospital. Almost all the persons whom I visited are recent immigrants, 44 from Russia and 4 from Austria-Hungary; all of limited means, several very poor; none having much education, some illiterate; the large majority, 39, living in the North and West ends of Boston.

One of my earliest impressions in this study was that, with the exception of one, none of these people — and 38 of them were women — was sick when I made my visits. In fact, 24 declared themselves perfectly well at that time. All were engaged in their usual activities. Thus I found one of these women hoeing the little garden in front of her house, — she was living in Malden. One of the men, who up to recently had been a frequent visitor at the hospital, I found cleaning up his grocery store; he is a cigar maker, and works at his trade all the week, helping his wife in the store on Sundays and in the evenings. Some, even, had to be reminded that they had ever been at the hospital, and it was only on questioning that I got their various complaints.

THE PREVALENT SYMPTOMS ARE PAIN, CONSTIPATION, AND APPREHENSION.

I have attempted in the accompanying table to give the symptoms somewhat in detail. Here I wish to emphasize three of them, — pain, constipation and apprehension. Of the 51 cases seen, only 7 did not mention pain. In more than half the number, the pain was located in the chest or epigastrium; a lesser number complained of headache or backache; a still lesser number of pain in the extremities or rheumatic pains; 12 spoke of pain "all over."

I found, however, that the term "pain" is used very loosely, especially by these Jewish people. Not only is their English vocabulary very limited, — 19 did not speak any English at all, — but their Yiddish is also very narrow. Thus pain may mean mere discomfort or distress, irritation or pressure, paresthesia or hyperesthesia. Even in their own language they misinterpret their sensations, more so when they have to express themselves in English. It has been supposed by some that the adjectives "*brennend*" and "*stechend*" are peculiar to the symptoms of these Jewish patients, that people of other races do not describe their pain sensations in such terms. I find, however, that they are used idiomatically in Yiddish. Moreover, I have heard not infrequently others than Jews describe their sensations of pain as "burning" or "cutting." Another error due to misinterpretation comes in the localization of the pain. The great majority of these patients speak of "pain in the heart," — "*es brennt mich, es stecht mich ins Herzen.*" Often this may be translated literally into "heartburn." Much more frequently, however, the term "heart" covers a larger region, including the whole chest and upper abdomen.

Constipation is very prevalent among these people, and I consider it, because of the pressure which it causes on the diaphragm and on the viscera, an important immediate factor in the etiology of their "pain" sensations. It was a symptom in at least 37 of the 51 cases. With the older ones it has been a matter of long standing; with the younger ones it has dated since their coming to this country. In the case of the

latter, it is due, of course, to the separation from home privileges and to the introduction to the sedentary habits incidental to employment in factories or stores. A typical story is that of one young married woman: "I was as strong and ruddy, when I came here, as all Russian girls are, but I lived with strangers, and worked from morning till night in a poorly lighted and poorly ventilated shop, with only a small, dry lunch for my mid-day meal. I soon began to grow weak; my eyes became dim, and my head commenced to ache, my teeth grew poor, and since then I have had stomach trouble." This constipation must be considered, however, not only as due to sedentary occupations and irregular habits, but also as a phase of the general muscular hypotonicity which has become characteristic of the Jewish people during the ages of persecution. It is presumably the same diminished muscle tone, causing displacement of the visceral organs and loosening of the ligaments of the extremities, in people who, during ages of extreme nervous tension, have developed an intense sensitiveness that accounts for many of the vague and diffuse "pain" sensations so common among Jewish patients.

I wish next to call attention to the element of apprehension which is very prevalent among these patients. Definitely I found that 14 of the 51 persons I saw, feared that they were suffering from cancer, consumption or heart disease. One woman told me that she heard people talk so much about consumption that she got it into her head that she also was suffering from it. Another, whose mother had died of cancer the year before, was very sure that the pain in her left side was also due to a new growth. Still another had on the day previous to my visiting her been to see one of the most prominent physicians in the city about her heart; she had already been to about all the clinics in Boston, and everywhere was assured that her heart was all right, but she thought that the doctors would always talk differently among themselves about her; this physician had also reassured her, and prescribed a laxative; still she believes that there is something wrong with her heart. To several of these people complaining of "pain in the heart" I put the question, "Would the pain bother you as much if it were in your little toe instead of your heart?" and in some cases I got the prompt reply, "Of course not; the heart is so much more important than the toe." The Jews, always a highly imaginative people, have been for centuries cradled in fear, so that it has become one of their keenest emotions, provoked by trifles.

THE ECONOMIC LIFE IN AMERICA IS MORE STRENUOUS THAN IN RUSSIA.

As to the duration of these ailments, I found that with 14 of the persons seen their symptoms came on before their coming to this country, and of these, half have felt worse since, while with 34 they came on in America. This is to be expected, considering the stress and strain incidental to establishing oneself in a strange land. In the accompanying table I try to compare in a way the modes of living of these people here in America and in Russia. Though the figures show that in the old country half of the persons under consideration lived in small towns and only less than half in cities, I wish to point out that essentially they were all city dwellers. In the small town as well as in the city in Russia the Jews live under crowded conditions, and are employed in sedentary occupations. On the whole, I believe that when they come to the American cities they do not live in a more crowded condition, at least as far as the number of persons per room is concerned, than in their old homes. The weather in Russia is much more equable than here, but I was rarely told by any one that the change affected him or her. The patient's industrial life, however, especially during the early years after arrival, is lived under much greater strain here than in Europe, for though the income is increased, the standard of necessities is raised out of proportion to income.

This strain weighs especially on the Jewish woman, for here as well as in Russia she very frequently has to share with her husband the burden of supporting the family. In my series of cases 7 of the women were the sole supporters of their families. It is rare here in America that a Jewish girl is at home not working, a thing not at all unusual in Russia. Married women help along by keeping boarders, or by working shoulder to shoulder with their husbands in business, aside from their household duties. Many a home in the North and West Ends is to be found in the rear of stores. One woman living under these conditions told me that she was up from seven in the morning till one at night, running back and forth from the kitchen to the store, — it was a little lunch room. Another of these women I found, when I came to see her, had been out collecting bills, — her husband keeps a grocery store, — the whole of a cold winter afternoon, though she was pregnant and quite miserable.

IRREGULAR HABITS, IMITATION, TRADITION AND THE GREAT NUMBER OF HOSPITALS ARE FACTORS IN THE ETIOLOGY OF THESE DEBILITIES.

Of course, one is not to look for regular habits under such circumstances. Meals are had at any time, and are never given a reasonable length of time. Those who work in factories either get home to swallow their dinners in the few minutes that they have, or else eat a dry meal in the shop. As for food I have observed that much more meat is eaten here than in Russia, and less fat. Tea is taken in moderation, less than in Russia; but more coffee is used here. Alcohol is not a factor.

Of recreation there is little either here or in Russia, — on the whole more here, though in Russia the Sabbath is much more a day of rest. Of the 51 persons seen, only 5 had had a vacation regularly for several years; 5 had had it only once. One young man who keeps a candy store in East Boston had had a two weeks' vacation the

summer before, but when he got back he had so much to do that he thought he had lost more than he gained, and said he would think twice before going again. With the majority the only change in the routine of life is the walk to and from work, the visit to the butcher's or grocer's, or the chat with the neighbors on the doorsteps.

As I have mentioned above, 38 of the 51 cases studied were women. Moreover, as far as my own experience goes, — and my experience has been chiefly with Russian Jews, — as well as that of many that I have questioned on this subject, almost all married Jewish women, whether of the hospital class or not, some time or other get into a debilitated condition, and present symptoms similar to those of the cases here analyzed. They are temporary affairs, but recur; all due to the mode of living, exhaustion or worry. I have observed, however, that imitation and tradition play some part in the etiology of these debilities. The undercurrent of thought on this subject seems to be that from time immemorial women have been sick; it is a sort of privilege tolerated with them; it is even expected of them. "A woman keeps on dying all the week, but recovers on the Sabbath," and "A woman has ninety-nine souls," are two Jewish sayings which show that this feeling is deeply rooted. It is the subject for conversation when women get together; to be sick gives one a standing in such circles. Gradually it creeps into the young woman's subconsciousness, and she, too, begins to visit the doctor or the hospital.

I know, however, that the Jewish women in Russia do not complain as much as when they come here. They all boast of their strength and good health there, and of the amount of work they could do. The change is due, of course, to the strenuousness of the transitional period which they are living through. I wish to call attention to another factor, a minor one though it may be. One often hears of the great percentage of people seeking medical advice at the hospitals, but one seldom considers that many people seek medical advice *because there are hospitals.* In Russia the Jewish woman can hardly afford to consult a doctor for the least thing that ails her, and hospitals and dispensaries are very rare. In the American cities, on the other hand, it usually so happens that the large hospitals are situated in the very centers of the crowded districts, not to mention the many dispensaries and the lodge-doctor system. These help the Jewish woman to keep her attention on herself; she goes to the hospital or to her lodge-doctor for things which in her old home she had to overlook and forget.

THESE DEBILITIES ARE NOT PECULIARLY JEWISH.

My aim has been to bring out and emphasize several points which have become clearer by this study. Is there such a condition as *Hebraic* debility? Is there a debility peculiar to the Jewish people? I cannot think so. I admit that the symptoms considered are, in their grouping, expression and frequency, peculiar to the abnormal circumstances under which only a part of the Jewish people live or recently have lived. There is not, however, anything essentially Jewish or Hebraic about them; there is nothing that makes them different from neurasthenic symptoms in other races. According to the testimony of physicians who come in contact with the prosperous and educated Jews, removed from those circumstances, their patients do not present the symptoms so commonly seen among the Jews coming to the hospital clinics. The same is true of the second generation of the Russian Jewish immigrants.

The Jew is markedly neurasthenic, but as the French author, Leroy-Beaulieu, says, "It is not to be attributed to his Oriental origin or to a peculiar anatomical structure. The predominance in the Jew of the nervous system over the muscular system is due to the mode of his secluded living, to the conditions of his existence, to his sedentary and city life, with lack of physical exercise and weakening of the muscles, to the emotions and cares of the occupations carried on by his fathers. For centuries he has owed his existence more to his brain than to his arm. Even now in Russia he succeeds in maintaining a miserable existence only by a miraculous will and industry." Here in America the effect which migration has upon the nervous resources of the Jew must be considered, and at the present time, also, the effect of the atrocities committed upon his "flesh and blood" in Russia and other black spots on the map.

In the Shattuck Lecture of 1899, Prof. J. J. Putnam, says, "This or that American or Irishman or Jew cannot be treated to the best advantage so long as he is regarded solely as an individual. His racial traditions and temperament should be taken instinctively into account." Because of the failure to do so, it seems to me, the treatment of the class of patients considered in this paper, both in private and hospital practice, is as unsatisfactory as it is. When a woman comes complaining of pain in the side or back, or of headache, or of any other such symptom, it is not enough to say, "Oh, well! She is a neurasthenic. Give her Mixture X or Tablet Y." The patient so treated will keep on coming to the clinic for some time, and then go to another, and so on. The physician, especially with these Jewish patients, must learn to appreciate their natural history, their temperament and traditions, their modes of living and suffering, — in a word, to understand them. Such an appreciation will lead to sympathy rather than to repulsion, and instead of taking half a minute, he will take three or five, reassure his patient, gain her confidence, and instruct her to control her "pain" sensations and to correct her diet and habits. A patient so treated, no matter how dull or ignorant, will show results; once or twice at the hospital will be enough for her; besides, she will become a missionary to her circle of friends.

I have mentioned before that the second generation of Jewish immigrants, relieved from many of the abnormal circumstances under which the parents labored, quickly get away from the

tendency toward debility. Moreover, these young people very frequently bring light into the households of their parents. I know personally of many instances where the parents have learned to lead more rational and comfortable lives through the influence of their children. It is through these young people, trained in American institutions and ideals, that the differences between the many elements of the population are to be removed.

SUMMARY AND CONCLUSIONS.

1. Debility is a common condition among the Jewish patients coming to the Massachusetts General Hospital; as a rule it is temporary, but is apt to recur.

2. The prevalent symptoms are pain, constipation and apprehension.

3. The etiology of these debilitated conditions is to be traced to the peculiar circumstances under which the Jews have lived and still live in eastern Europe. Here in America the economic strain during the early years after arrival is an important factor.

4. Debility is especially common among the Jewish women of the immigrant class, because the economic strain weighs very heavily on them. With them, also, imitation and tradition and the ease with which medical advice can be obtained are factors to be considered.

5. These debilities are peculiar not to the Jew, but to the abnormal conditions under which he has been living. As soon as he is relieved from these conditions his symptoms are not different from those of other races.

6. Finally, in the treatment of the cases considered it is well to bear in mind the importance of the old sentiment, "not the disease only, but also the man."

ANALYSIS OF CASES.

Massachusetts General Hospital.

CLINICAL MEETING OF THE STAFF, NOV. 22, 1906.

I. TWO CASES OF EXCISION OF ADENO-CARCINOMA OF THE RECTUM, WITH PRESERVATION OF THE SPHINCTER.

II. CANCER OF PROSTATE. COMPLETE PROSTATECTOMY BY LORING'S METHOD.

III. DIVERTICULUM OF BLADDER. EXTRA-PERITONEAL REMOVAL WITH SUTURE.

BY C. A PORTER, M.D.

I. I WISH to show two cases of adeno-carcinoma of the rectum, at present alive and free from recurrence; one seven years, the other five years, after operation. The first case I reported here two years ago, and show him to-night because he still remains well, at the end of seven years. The other case is as follows:

Arthur Moore, age forty-four, living in East Everett, was admitted to the Massachusetts General Hospital, Dec. 1, 1902, to the service of Dr. C. B. Porter.

On entrance, urine was of normal color; acid reaction; specific gravity, 1,019; no albumin; no sugar. A month later (Jan. 8), urine the same with the exception that the specific gravity was 1,024.

Family history negative. He had always been well, and had worked hard. Many years previously had rheumatic fever, which was his only illness. He has had piles for twenty years, but they have never troubled him until about a year ago. Always been constipated. Denies venereal.

One year ago, piles began to itch and burn; bled frequently, and came down outside anus at every movement of the bowels; has used various salves without relief. Complains chiefly of bearing down in rectum, coming on before a movement of the bowels; also the annoyance which the piles cause him. No bad pain in rectum; no mucus or pus discharges; no loss of weight.

P. E. Poorly developed and nourished. Heart, lungs and abdomen negative. Rectal examination: on anterior wall of rectum, about three inches up from anus, is a soft, spongy tumor, irregular in outline, size of a small hen's egg. Few small glands in groin.

Operation, Dec. 4, 1902. C. A. Porter. Ether. Patient lying on abdomen, with thighs moderately flexed. Sphincter dilated; rectum irrigated with corrosive 1–1000, and salt solution.

Incision 9 cm. in length, extending along cleft of nates, into rectum. Sphincter cut; incision carried down to bone. Coccyx separated from soft parts with periosteum elevator, and removed with bone forceps. Incision carried around rectum mucous membranes, just above external sphincter, and carried through the walls to the perirectal tissue. Keeping in the blunt of cleavage, the rectum was separated and isolated for 12 cm. of its length. Walls of rectum were somewhat adherent to prostate, but were separated cleanly. Peritoneal fold of anterior wall of rectum was pushed backward and upward, and peritoneal cavity was not opened. Mucous membrane which was left covering sphincters was dissected off the cylinder of rectum, containing growth, and completely isolated, was cut away and removed; bleeding points tied. The incision was 2 cm. above its highest demonstrable limit of growth; one or two small perirectal glands were removed also. The divided end of the gut was then sewn to skin about margin of ends; this was done easily without undue stretching. The ends of the divided sphincters were approximated, thus encircling the transplanted gut very effectively. One silkworm stitch taken to close section wound. A drainage tube put down to the left of gut, and rubber dam to right. T. bandage.

Kraske operation (modified) for carcinoma recti.

Patient was breathing laboriously and had poor color throughout operation. Sent to ward in fair condition; shock enema.

Reported later for poor pulse, which was irregular and easily compressible, although of good volume.

Wound discharged very little; no pain or discomfort. Patient was unable to evacuate bladder completely, and the residual urine increased, so daily catheterization was resorted to.

Examination of 19th showed that sphincter grasped finger very strongly, but apparently voluntary nerves are cut, for patient has no control. Bowels are loose, and movements occurred without knowledge of patient.

Four months after operation, patient regained control of urine, and slowly regained control of sphincter ani. Was discharged Nov. 4, 1903; holds feces well for three to four days; sometimes a little blood comes away, but there is no pain. Examination of rectum shows scar wound, with no signs of recurrence.

An ulcerated infiltrating new growth about 4 cm. in diameter with a slightly papillary and infiltrating edge 5 cm. above rectum.

Microscopic examination. — Shows irregular glands which had infiltrated the submucous tissue and, in some places, apparently has solid masses of epithelial cells.

Adeno-carcinoma. Dr. Whitney.

In both of these cases, the sphincters have been preserved; both had an ulcerated adeno-carcinoma on the anterior wall of the rectum about 4–5 cm. in diameter. In the first case, an incision was made from the lower end of the sacrum down through the sphincter ani in the median line behind. The coccyx was removed. This incision was continued in the median line, through the posterior wall of the rectum, both edges of the wound being then widely retracted, disclosing the ulcer on the anterior wall. This was freely excised, and the tissues behind the prostate and about the vesical seminals cleaned out. This circular wound was then closed with buried catgut stitches, from above downwards. The posterior incision in the rectum was closed in the same manner, laterally, and the sphincter muscle sutured. A rubber tube was placed in the rectum, with posterior iodoform gauze drainage on either side. In the second case, the same incision was made down to the rectum. The sphincter was divided, and the rectum cut just above the internal sphincter. The rectal tube with surrounding fat tissue, was then freed and divided transversely an inch above growth. The upper end of the rectum was then brought down and sutured in a circular fashion, and the mucous membranes just above the internal sphincter. Both sphincters were then sutured; rubber tube in the rectum, and posterior gauze drainage as before.

In both cases there was some fecal leakage but the sinuses were closed in six weeks.

II. Patrick J. Kelley, aged fifty-one, residing in East Boston, was admitted to my service, July 26, 1907; recommended by Dr. Lincoln in the Genito-Urinary Department. His history is as follows: Denies venereal; moderately alcoholic; bowels costive; indigestion at times; has lost no weight. Well nourished muscular man. For several months has been troubled with frequency of micturition at night, which wakes him three to four times. Four weeks ago, had to pass urine frequently during the day with scalding sensation. Has never had pain other than on urination. Rectal examination shows small, indurated and nodular prostate; not tender. No glands by rectum; no glands in groin. Testicles and cord negative. Urine acid; no albumin; no sugar; specific gravity, 1,015.

Cystoscopic examination by Dr. Davis, July 25. "Kollman instrument introduced with considerable difficulty, requiring great depression of the handle. Some spasm of neck of bladder. Fundus trabeculated; whole floor of bladder ulcerated. Right lobe of prostate presents rounded tumor, size of marble, which runs off into a generally elevated surface, presenting little reddened excrescences suggesting a new growth. There is a black mass, about size of strawberry, which cannot be fully brought into view, and which moves from one part of the bladder to another. There was some hemorrhage. Ureteral openings not distinctly

seen. Diagnosis of incipient prostatic carcinoma made and radical removal advised. This diagnosis was concurred in by me from the rectal examination, owing to the nodular condition and the extreme hardness.

Operation, July 31, 1907. The patient in Trendelenberg lithotomy position. Horseshoe incision made in perineum and dissection made exposing the bulbous urethra and the prostatic lobes; considerable bleeding. An oblique incision was then made through the right lobe of the prostate, and a wedge-shaped piece given to the pathologist for examination. The report from the frozen section given to Dr. Kidner, and confirmed by Dr. Richardson, was probably carcinoma, and the radical operation decided upon.

A median incision was made just back of the membranous urethra and Young's retractor introduced. The prostate was pulled down with strong traction, and with scissors and blunt dissection, the surrounding structures were freed from the prostatic capsule. The bleeding was very troublesome, controlled by snaps and pressure. After the posterior and lateral parts were thoroughly freed, the urethra was divided at its membranous portion; the whole mass pulled downward, and with great difficulty and copious hemorrhage, the prostate was freed from its pubic attachments. The bladder was opened anteriorly, two strong silk sutures being inserted at the edge in order to prevent retraction. The base of the bladder was then divided with scissors, well behind the internal sphincter, and the vasa deferentia and two thirds of the vesical seminal removed "*en bloc*." A No. 12 English soft rubber catheter was then introduced through the urethra into the bladder, and with 00 chromic catgut sutures, the membranous urethra was sewed about it to the bladder, and the stem of the Y-shaped opening in the bladder closed in a similar fashion. This proved to be a very difficult manipulation, and the patient had to be lowered from the Trendelenberg position owing to the retraction of the bladder. A number of tension sutures were placed about one inch from the urethral suture, passing through the muscular walls of the bladder and posterior part of the pubic bone.

Iodoform wicks inserted by the side of the newly formed urethra, extending on either side into the pubic region.

Operation lasted for three hours, and the patient was put to bed, suffering both from shock and hemorrhage. The operation seemed to me both a very severe and a difficult one. Convalescence, however, was satisfactory. At the end of five days there was some sloughing of the fat tissue, and some leakage due to suture. The catheter remained in position forty days, at the end of which time, methylene blue showed no leakage in the perineal wound, which was almost closed. Patient was discharged Sept. 19, about two months after entrance.

The specimen consists of symmetrical prostate, 4.5 by 5 cm. in diameter; its two lobes being practically equal and not markedly lobulated. The capsule appears covering the whole mass. There is also a piece of the floor of the bladder about 2 by 2 cm. containing the internal meatus and the prostatic urethra. Behind appear the seminal vesicles, which are dense and thickened. Also the vasa deferentia, which are filled with muco-purulent fluid. Both these structures are greatly thickened, hard, and suggest malignant feel. On section, the prostate is unusually homogeneous in structure, although the minute glands can be made out, scattered all through the cut surface. The structure seems to be unusually cellular. The capsule is not markedly adherent to the prostate itself.

Microscopic examination through the prostate and capsule shows the glands to be everywhere extremely irregular and to be increased markedly in numbers. The muscle tissue is somewhat infiltrated with round cells, but not greatly changed. The whole increase in bulk is apparently in the number and size of these glands, some of which are clearly defined with firm basement membranes; these, however, at one point or another, entirely lose their basement membrane, and the cells can be seen growing freely in the muscular tissue, separated from any gland. All of the glands show marked hypertrophy, in the epithelial structures, many of them being noticeably papillomatous. As far as could be made out, however, the capsule is not infiltrated.

Section through the vasa afferentia and seminal vesicles shows again great increase in the epithelial lining of these structures. In places the mucous membranes seem to have broken through its basement membrane and to be infiltrating the muscular layers of the tissue.

Adeno-carcinoma of prostate.

Patient reported to me a week ago at my office. He can hold his water an hour and a half at night, but is incontinent during the daytime, wearing a urinal. There is a definite narrowing, admitting No. 24 French at the site of the suture. The urine shows slight cystitis. He has no pain; has gained weight and color.

Rectal examination shows in region of the left vesical some fullness, but no nodulation.

This case is interesting, I think, in two respects: first, because an attempt was made, by saving the membranous urethra, to restore partial continence. In the operation as planned by Young, the membranous urethra is removed. Up to the present time, however, this attempt has been unsuccessful. Second, the question of diagnosis and a choice of cases for this formidable operation. From my experience with this patient, and the few reported cases, it would seem an absolutely unjustifiable operation to do in case there was any reasonable doubt as to the presence of carcinoma. On going over other sections of this prostate, mounted in paraffin and more careful staining, there is at present some doubt whether cancer was actually present, but it is certain that there was an abnormal tendency for adenomatous tissue to be found in the surrounding tissues, suggesting at least the probability that adeno-carcinoma would develop, or might be found in other places on further section. In subsequent cases, I should advise enucleation of the gland, if the frozen sections did not show definite carcinoma, or the clinical signs were absolutely characteristic.

III. Hudson H. Smalley, aged thirty-four, entered Dr. Cabot's service in April, 1906, with the diagnosis of cystitis. Twelve years before, he began to have bladder trouble; frequently scalding micturition, often passing fragments of tissue size of a pea, and once a piece as large as palm of hand. He was treated at the Maine General Hospital for ulceration of bladder. Denies venereal.

At present he complains of passing both fresh and clotted blood with a bad odor. Has difficulty in starting stream; dribbles, and he feels that he never fully empties his bladder. He has frequency of urination every half hour or more during occasional attacks of cystitis. Appetite is good; bowels regular.

Bladder is full, extending to umbilicus; no fever. Urine: specific gravity, 1,015; slight trace of albumin; alkaline reaction. Sediment: some pus; bladder cells; triple phosphate crystals; numerous blood corpuscles, both normal and abnormal; many bacteria. Catheterized and 19 oz. of residual urine found. On the next day, residual urine 24 oz., and on the fourth day could not be catheterized on account of spasm. Decided to go home against advice.

Patient entered hospital again April 16, 1907; has lost weight and looks badly. Rectal examination shows prostate moderately enlarged; base of bladder uneven, tender, boggy and indurated. No. 11 English soft rubber catheter passed with some difficulty, drawing off 27 oz. ammoniacal urine. Patient put on constant drainage, and three days of such treatment cleaned up the urine somewhat, and patient was much more comfortable. Cystoscopy by Dr. Davis, who found three diverticula from the bladder, one large one extending from the left side of the base, backwards and downwards.

April 30. Operation by Dr. Mumford. Transverse incision above pubis; prevesical space opened; bladder wall thickened and friable; opened and a quantity of foul smelling fluid escaped. Upon exploration, two diverticula found, one about length of little finger, extending backwards and downwards. Radical operation was not attempted. A catheter was sewed into the bladder with a puckered stitch; wound closed with drainage.

May 7. Copious leakage about tube and gauze wick; tube removed, and inlying catheter inserted. Patient sat up in bed; free drainage from the suprapubic wound and urethra. On the 10th moderate suppuration of prevesical space. Bladder irrigated with argyrol, 5%; urine much clearer. On the 21st, second operation by Dr. Mumford.

Operation. — Bladder opened suprapubically, and found almost as foul as at previous operation. Diverticula examined and found to be sacular, with a tight sphincter at the orifice. These sphincters were both widely dilated, and the diverticula packed with iodoform gauze. Rubber tube inserted through suprapubic wound and a No. 10 soft rubber catheter through urethra; prevesical space drained with gauze.

On June 8, wound fairly clean; temperature normal; some drainage through suprapubic sinus; urine much clearer. On the 19th, suprapubic wound leaked copiously; hardly any urine by urethra. On the 24th, patient etherized and pus pocket found on anterior wall of urethra; 32 sound passed, and good drainage established through a No. 11 English web catheter. On the 25th, the powerful action of the muscle drove out the catheter.

June 30. Operation by Dr. Jones. Posteriorly, urethra explored through the wound, and several pockets found. Index finger passed into the bladder, and a large rubber tube inserted and sutured in position.

July 3, patient has been draining well; little suprapubic leakage; urine less foul; no dependent drainage and frequent irrigation of bladder. On the 14th, catheter through urethra. On the 22d sleeping and eating better; urine clearer; draining well.

Aug. 2, patient discharged, but urine still foul; unless on constant drainage, some suprapubic leakage.

Re-entered hospital in my service, Sept. 20, 1907. Had been doing badly in the Out-Patient Department, and for the last five days pain in left renal region, and marked swelling of the left epididymis. Examination shows definite tenderness in the region of left kidney, with albumin and numerous casts in the urine, which is foul and full of pus. Patient had apparently developed a recent pyelitis as well as an epididymitis. Has lost weight and is utterly discouraged. On Sept. 8, I decided to make an attempt to remove the diverticula by Young's method.

Patient in Trendelenberg position; five-inch suprapubic incision to left of old scar. Everything was bound together by cicatricial tissue. Incision then made parallel to Poupart's ligament on the left, outward, for a distance of three inches. Dry gauze dissection backward and to the left, freeing the upper part of the bladder which had been distended with boric solution. The peritoneum was opened and through this the base of the bladder was examined. After carefully walling off with gauze, an elastic mass about the size of a banana, and three inches long could be made out extending backwards and to the left of base of bladder firmly adherent to rectum and surrounding structures. After freeing the bladder and diverticulum, it could be seen that the vas deferens ran obliquely inwards and backwards, anterior to the sac. An attempt was made along a line of cleavage to separate the rectum from the diverticulum, but this dissection was found to be too dangerous, so the bladder was opened suprapubically, and after much difficulty, the forefinger was hooked into the diverticulum and, the bladder with it, forcibly pulled forwards. After this maneuver with dry gauze, scissors and the finger nail, the rectum and surrounding tissues, after a half hour's dissection, were gradually separated from the wall of the sac. The diverticulum was then grasped with double hooks and firmly withdrawn, and cut off with scissors from the base of the bladder. The opening left was sutured with two layers of buried catgut stitches. The left urethra was not seen at any time, but the left seminal vesicle was exposed in the dissection. The peritoneum was closed. The bladder washed out carefully, and sutured in layers, about a suprapubic tube. The bed left, after the removal of the diverticulum, was packed with iodoform gauze, and a soft rubber tube and catheter was placed in the urethra. The operation I consider an extremely difficult one, requiring three hours of hard work. On the day following, however, the patient was in fair general condition.

Sept. 27. Bladder draining well, both above and below.

Sept. 29. On doing dressing this morning, part of peritoneum overlying upper part of wound was found to have protruded through the wound with a loop of intestine within it. There were no signs of strangulation, and the little perineal hernia with its contents was pushed backward and held in place with gauze without further trouble.

Oct. 3. Bed rest. Amount of drainage daily increases; patient very comfortable, with normal temperature; good drainage through urethral catheter; bladder washed out twice daily. No leakage through wound into dressing.

Oct. 4. This morning, the urethral tube was found to have drained hardly any, and the suprapubic dressing was soaked. The tip of urethral catheter protruded through suprapubic wound, which has opened, so that the suprapubic drainage tube was quite loose. The latter was therefore removed, and the catheter poked back into the bladder. Pelvic packing removed, and replaced by plain gauze, and upper angle of wound tightly restrapped with adhesive plaster.

Oct. 6. Wicks all removed and replaced with similar ones; two in number passing down between bladder and rectum. The upper angle of wound drawn together with adhesive plaster.

Oct. 7. Patient draining well this morning, with normal temperature, and little suprapubic leakage.

Oct. 8. Wound cleaning up well, and much less

painful; wicks between bladder and rectum removed and renewed.

Oct. 10. Catheter again protruded through suprapubic wound; replaced. Wicks removed and only one replaced.

Oct. 13. Catheter protruding and again replaced; wick renewed. There is some temperature and purulent discharge.

Oct. 15. Wick changed; there is still profuse purulent discharge through a deep sinus into the pelvis, behind the bladder; catheter draining well.

Oct. 16. Patient comfortable with normal temperature, and draining well.

Oct. 17. Sinus discharging freely; re-wicked.

Oct. 19. Redressed; not draining well; leaks through suprapubic wound.

Oct. 20. Drain of 36 oz.

Oct. 21. Catheter readjusted.

Oct. 22. Drain 67 oz.

Oct. 24. Drain 14 oz. Wound looks about the same.

Oct. 27. Drain 69 oz. On doing the dressing, the tip of the catheter was found protruding through the bladder sinus; pulled back. Has not leaked any; now there is a five-inch sinus going down into the pelvis, which is closing in and discharging less.

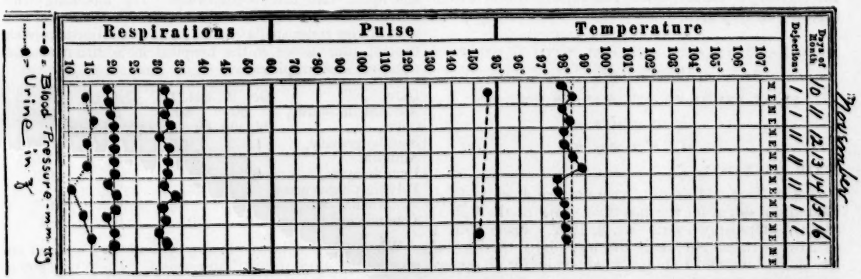
Present condition of patient: it has been most difficult to maintain urethral drainage, but when it is working well, there is little suprapubic leakage, but the eye of catheter is continually protruding in the suprapubic wound or becoming stopped up. At present, there is a small granulating sinus. The suprapubic opening in the bladder is apparently closed, but there is still some urinary leakage at the site of the suture. Over fifty ounces of fairly clean urine is discharged by the catheter every twenty-four hours.

The patient's general condition is much improved.

I. A CASE OF STOKES-ADAMS DISEASE WITH EXHIBITION OF THE PATIENT.

BY H. F. VICKERY, M.D.

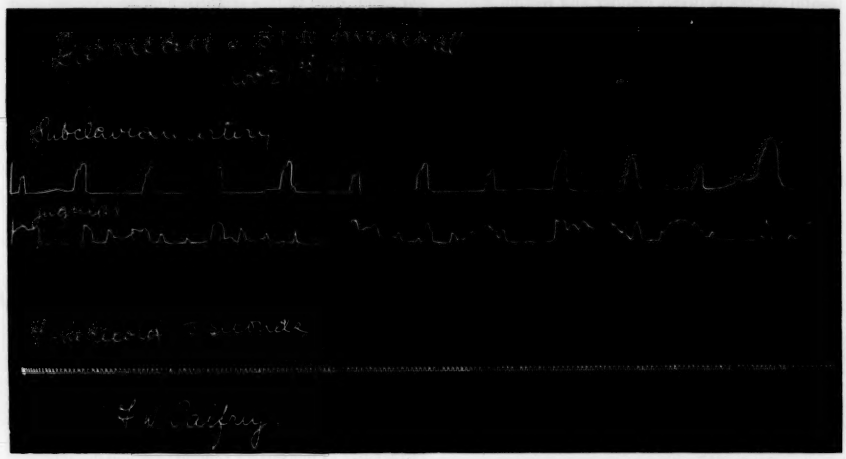
A. G., a male cook, sixty-eight years old, entered my wards at the Massachusetts General Hospital, Sept. 9, 1907. His family history was good, except that his mother had died of heart disease at the age of seventy-one. His habits were temperate. Venereal disease was denied, but exposure confessed. For eighteen years he had been subject to convulsive seizures, occurring usually without warning, and sometimes as often as two or three times in a month or again once in two or three months. Occasionally he bites his tongue in them. Eight weeks before entrance he noticed swelling of the abdomen, but he has had no dyspnea nor cardiac pain, and he has been doing light work.



Physical examination showed a pale, well developed, poorly nourished man with a pulse and apex beat of 30 to 35 per minute. (See sample of chart.) The radial arteries were tortuous and hard, with irregular platelets of calcification. The posterior peroneal arteries could not be felt to pulsate. The systolic blood pressure was 150 to 160 mm. of mercury. The heart's apex was three quarters of an inch outside the left nipple, in the fifth space. The heart sounds were regular, slow and forcible. There was a systolic murmur at the apex, transmitted a short distance to the left. The pulmonic second sound was slightly accentuated.

A jugular pulse was seen, not easily counted, but apparently two or three times as frequent as the apex beat. It was not possible to detect by auscultation any sounds suggestive of more frequent contractions of the auricles or of the right ventricle, as distinguished from the systole of the left ventricle. Dr. F. W. Palfrey has made simultaneous tracings of the pulsations of the right jugular vein and right subclavian artery. (See cut.) Fluoroscopic examination had an indecisive result; of six equally competent observers, three thought they could see pulsations of the auricles more frequent than of the ventricles in the ratio of about 65 to 25; the other three observers could not verify this. As the examination fatigued the patient, it did not seem justifiable to prolong or repeat it.

The abdomen was twice tapped:



Amount, culture.	Eight pints, sterile.	Three pints, sterile.
Specific gravity,	1,009	1,011
Albumin,	¾%	1¼%
Tubercle bacilli,	0	0
Lymphocytes,	82%	86%
Endothelial cells,	17%	13%
Polymorphonuclears,	1%	1%

The fluid was regarded as a non-inflammatory transudation. At the present time, the patient having been confined in bed for ten weeks, there is scarcely any liquid in the peritoneal cavity. At the time of entrance, the eyelids and the lower extremities were slightly edematous; but this swelling has been absorbed.

The urine has a slight trace of albumin with a few hyaline casts.

The liver is slightly enlarged. No change in the spleen can be detected. There is no striking change in the veins connected with the portal circulation.

CASE IV.

The patient, although never intoxicated, has drunk more or less alcohol for forty-five years, and it does not seem possible to exclude absolutely the existence of a limited degree of hepatic cirrhosis.

About a month after entrance several convulsions occurred in the course of a few days. One of these was watched by my house-officer, Dr. L. H. Burlingham. He states that both heart and respiration ceased. Apnea lasted two minutes and the heart began to beat before the resumption of respiration. In some of the attacks there was an escape of urine and feces.

It is to be remarked that these convulsions first began when the patient was about fifty years old, late in life for true epilepsy, and that the length of time since they appeared, together with the physical examination of the patient, justify us in ruling out almost all other causes except the Stokes-Adams disease; so that it seems probable that this latter condition has existed for eighteen years. Osler has reported one which lasted thirty years.

MALIGNANT DISEASE OF PLEURA, WITH EXHIBITION OF SPECIMEN.

BY H. F. VICKERY, M.D., AND OSCAR RICHARDSON, M.D.,

WITH REMARKS

BY J. H. WRIGHT, M.D.

DR. VICKERY:

Mrs. J. T., a widow sixty years of age, born in England and resident for the last two years in the United States, entered my wards Oct. 9, 1907. From Nov. 1 to Nov. 9 (when she died) she was under the care of Dr. R. H. Fitz, and I am indebted to him for an opportunity to report the case.

There was no family history of tuberculosis or cancer. There was no evidence of syphilis. The menopause occurred at fifty-three, without symptoms. The habits and previous health had been good. A year ago she was ill in a hospital for one week with diarrhea and vomiting, and she has been "run down" ever since. About eight months ago, she fell into a hole in a floor, and hurt her foot and right side; since then she has had occasional pain (sometimes severe) in that side. For seven weeks the pain has been much worse and almost constant, and her general health has suffered. She has had slight dry cough, dyspnea, fever at night, gastric distress and nausea without vomiting. In bed for almost five weeks. Four weeks ago, five pints of bloody fluid were withdrawn from her right chest, and an equal amount six days later. Expectoration is very scanty — a little clear mucus.

The patient was well developed and well nourished, somewhat cyanotic, never cachectic. The heart's apex was in the eighth interspace, 6¼ inches to the left of the mid-sternum beyond the anterior axillary line. The sounds were of good quality without murmurs. The pulmonic second sound was slightly accentuated. The radial pulses were synchronous, equal, regular and of good volume and tension. The right chest was very dull where it was not flat, with respiration, vocal resonance and vocal fremitus almost absent, except at the apex. No râles were heard. The left lung was normal (except for Grocco's sign). Pressure on the ribs in the right axilla causes pain. The patient was tapped four times in the hospital in addition to the two previous tappings:

Date,	Oct. 9	Oct. 14	Oct. 17	Nov. 3
Amount in ounces,	90	80	25	19
Color,	bloody	bloody	very bloody	
Specific gravity,	1,019	1,016	1,014	1,015
Albumin,	3%	3.5%	3%	1.6%
Lymphocytes,	97%	97%	94%	90%
Polymorphonuclears,	3%	3%	2%	....
Endothelial cells,	....	....	4%	10%
Tubercle bacilli,	0	0	0	0

When the needle was inserted, it always seemed to go through more tissue than normal. There was some relief afforded by tapping but not much improvement in the physical signs nor in the position of the heart.

The x-ray showed a diffuse shadow over the whole right side not changing with change in the position of the patient, also a mass near the hilum of the left lung.

The pain required increasing doses of morphine,

up to ¾ gr. during the night. Dyspnea increased more rapidly than the heart failed. The pulse remained good till the last half hour. The temperature ranged between 98° and 101°, the pulse between 80 and 110; the respirations were usually 28, before the end rising, however, to 45. The urine was negative. The per cent of hemoglobin was 85, the white count, 4,800. there was never such a temperature as to permit a tuberculin test.

Malignant disease was thought of from the first, but tubercular disease perhaps involving mediastinal glands was not considered impossible.

I. DERMATITIS HERPETIFORMIS (HERPES GESTATIONES). II. RAYNAUD'S DISEASE.

BY H. P. TOWLE, M.D.

I. This woman who is now in the fifth month of her fifth pregnancy states that at about the third or fourth month of each of the four preceding pregnancies an eruption similar to that now present has appeared which persisted until after delivery. With the termination of pregnancy the eruptions cleared up gradually and the patient remained free until the next pregnancy. The attacks have increased in severity with each outbreak, the present being the most severe of all. The eruption itself is also of interest as it shows to an unusual degree the multiplicity of lesions characteristic of the disease. Upon the front and back of the trunk are large erythematous plaques of irregular wavy outline together with scattered small circinate lesions. Upon the lower arms especially, the lesions are very suggestive of erythema multiforma with their prominent peripheries, clearer centers and central dark spots. Upon the inner surfaces of the thighs and in the groins are the characteristic almost purple areas left by preceding lesions from which spring vesicles and bullæ of varying sizes and varying outlines, everywhere arranged in groups. Upon the lower legs and to a less degree upon the thighs are pustular lesions in addition to vesicles and bullæ. Vesicles and bullæ are also to be seen in groups upon other parts of the body. Pruritus is a marked feature of the case and is so severe as to prevent sleep.

II. Signs of a disturbance of the circulation are to be seen in all the fingers of this woman to a marked degree and to a lesser extent in the ears. Variations in color from dead white to a static blue are constant and often rapid. Upon entrance the anemic condition seemed to predominate, but recently the congestive has been the more frequent state. This is particularly true of the terminal phalanx of the middle finger of the left hand over which the bluish color is appearing more and more frequently for gradually lengthening periods. Subjectively, the patient complains of coldness and pain in the hands and arms almost continuously.

I. SUPRAPUBIC PROSTATECTOMY AND STONE IN BLADDER.
II. RUPTURE OF THE INTESTINE.
III. ECHINOCOCCUS CYST OF LIVER.

BY F. G. BALCH, M.D.

I. W. B., seventy-eight years old, entered my service at the Massachusetts General Hospital, July 8, 1907.

His family history is interesting in that his father was over seventy years of age when he died and his grandfather lived to be one hundred and twenty years old.

Six years before entrance he had an attack of bloody urine. Before that time he had had no pain, but after that the pain was severe and was referred to the end of the penis on micturition. He had seen blood six or seven times following exercise. He was having some difficulty in micturition and the frequency was especially distressing, often forcing him to get up six or seven times at night. There was no dribbling. More recently he had had less pain in the penis, but more in the rectum, especially on walking. The urine was foul and thick. There was a small hydrocele on the left. He thought he had lost 25 lb. in the last three years. Appetite was good. There was very slight sclerosis of the arteries. Tongue very dry and cracked. Heart and lungs were not remarkable.

Rectal examination showed the prostate much enlarged, especially on the right. It was not tender nor nodular. An attempt at cystoscopy was not satisfactory. The instrument went in with difficulty and caused much hemorrhage. A suprapubic cystotomy was done. Two stones lay in the bottom of the bladder, one a small round one about the size of a small cherry and the other irregularly shaped, being an almost exact representation of the small iron jackstones which children play with. The prostate was of large size, but shelled out very easily. The wound was partially closed and two drainage tubes put into the bladder. For the next forty-eight hours constant irrigation with salt solution was continued. In three days both tubes were removed and the next day he passed some water by urethra. On the eighteenth day the leakage had ceased and he was discharged on the twentieth.

Pathological examination of the prostate made by Dr. Kidner showed cystic hypertrophy of the prostate. There was no evidence of malignancy.

I am indebted to Dr. Edmund D. Chesebro, of Providence, for some further notes on this case.

He wrote me Nov. 11, saying the patient had been to see him three times. On Aug. 9, he had a small sinus which had closed up on the 27th. He was having a good deal of trouble with flatulency and constipation and various aches and pains in all parts of his body. There was some irritation of the bladder and mucus in the urine.

A letter written Nov. 8, by the patient, says he still has a great deal of pain like rheumatism, especially in his back and legs. He has a great deal of eczema about the anus and it extends out on to his legs and forward on to the scrotum. This was there before operation. He has various stinging sensations about the wound, and the urine is at times ammoniacal and still has a large amount of mucus in it. He passes a good stream but has to get up three or four times at night and passes water quite often during the day. If he tries to hold it long, he has some pain.

I wrote him advising him to take urotropin for his cystitis and since then have not heard from him.

II. L. F. W., twenty-three years old, was sent to the Massachusetts General Hospital by Dr. Robert T. Porter, of North Easton.

The family history and past history were unimportant.

The history as given at the hospital was that the night before entrance, the man was riding a bicycle at about 8.30, and while going down hill fast, he struck a stone; this threw him violently against the handle bars and over on the ground. He got up and went home. Severe pain began at once in the abdomen and was persistent. There was considerable nausea but no vomiting. Bowels had not moved since the accident. The urine was clear.

On the day of the accident he had ridden to Taunton, starting about 9 A.M., and presumably after having had some breakfast. He drank more or less all day, beer, ale and whiskey. He ate one or more ham sandwiches,

but nothing else. I have been unable to find out just what time he had these sandwiches, but probably somewhere about noon. He is a chronic alcoholic.

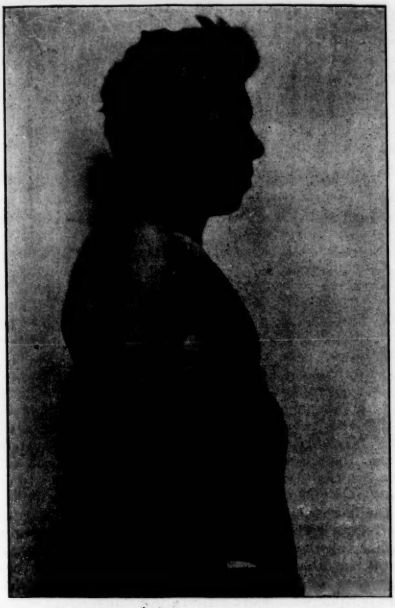
Dr. Porter saw him about 5.30 in the morning and brought him to the Massachusetts General Hospital.

Examination in the Accident Room showed nothing abnormal in the chest. The abdomen was very rigid over the entire left side and over the lower half on both sides. The right upper quadrant was slightly less resistant. There was marked tenderness on the left side over the region of the bladder. The lower half of the abdomen was dull but there was no shifting dullness and no masses to be felt. Temperature 101°, white count 12,000.

The abdomen was opened by a 4-inch incision in the median line. A moderate amount of blood-stained fluid escaped. Examination of the intestines in the lower abdomen showed nothing to account for his condition. In the left upper quadrant a mass of slightly matted intestines was felt and on withdrawing the hand a moderate amount of intestinal contents followed. The incision was enlarged upwards and the intestines systematically searched, from the cecum up, for a rupture. A large hole was found high up in the jejunum. This was closed with a continuous suture of chromic catgut. A second continuous Lembert suture of Pagenstecher was placed. The peritoneal cavity was thoroughly flushed out with salt solution. A cigarette wick was placed in the pelvis and another in the region of the tear in the intestine.

The patient made an uninterrupted recovery. The cigarette wicks were replaced in four days with small wicks of rubber tissue. He was discharged to the Out-Patient Department in twenty-six days. His temperature was at no time over 100° and the pulse, which was at the time of the operation 130, fell to 60 on the fifth day.

The fact that the patient had eaten but little on the day of the accident, and that was early in the day, that it had gotten below the uppermost portion of the small intestine, probably had much to do with his recovery.



III. A. G., twenty years old, entered the hospital from the Out-Patient Department on July 5, 1907.

He had never been sick before. One month before entrance he noticed a swelling at the right costal border. This was painful and prevented him from working. It appeared suddenly but had not increased in size. He had never been jaundiced.

Examination showed a healthy young man in other respects. There was a smooth, rounded swelling in the upper right quadrant of the abdomen which bulged the lower ribs forward. It was the size of a large orange, tense but not tender. It descended with respiration. The liver dullness extended to within one inch of the umbilicus. The sharp edge of the liver was easily felt. Its surface was smooth, otherwise the abdomen was negative.

I operated on July 8, 1907.

On opening the abdomen a mass the size of a grape fruit was disclosed coming out of the center of the liver well up above the lower margin. It was tapped and several ounces of clear watery fluid were withdrawn. After drawing off a large amount the tumor collapsed and the fluid became bile stained. The opening was then enlarged showing the collapsed wall of a single large echinococcus cyst. This was removed and the cavity packed with gauze. During convalescence large amounts of bile came from the wound. After the gauze was removed it was replaced by a drainage tube. An attempt was made to leave this tube out on the 22d, but the patient had a chill and it had to be replaced. This occurred on two later occasions when attempts were made to leave the tube out.

CASE 3.

Finally, on the 21st of August, he was discharged to Waverley. At that time the wound was still discharging slightly.

ECHINOCOCCUS CYST OF THE LIVER AND OF THE GALL BLADDER.

BY D. F. JONES, M.D.

THE following case was operated upon in Dr. C. A. Porter's service, and I am indebted to him for permission to report it.

A. P. J., aged forty-nine, a Swede, machinist by trade, entered the Massachusetts General Hospital Aug. 24, 1906.

In February, 1906, he was jaundiced for three weeks. After the jaundice, a small, hard, painless lump was noticed in the epigastric region. This grew gradually larger, but was never painful. He came to the hospital only because of shortness of breath.

He was born in Sweden, and came to America twenty-four years ago. He went home on a visit, and came back here sixteen years ago, and has lived ever since in Cambridgeport. He has had nothing to do with animals.

Physical examination showed a large, median, epigastric tumor, extending from below the umbilicus upward to the costal border, somewhat tender on pressure.

He was operated on, Aug. 25, 1906. A median incision was made. A large, thick-walled cyst was found on the under surface of the liver. The wall appeared to be made up of liver substance. The omen-

tum, stomach and transverse colon were adherent to the surface.

After walling off thoroughly with gauze, the cyst was incised. Immediately a cloudy fluid, filled with grape-like bodies varying in size from a pea to an egg, escaped. The cyst must have contained two quarts in all. The inside of the cyst was curretted with the fingers and with pads of gauze, and finally packed with two handkerchief gauzes. The wound was closed, except for the drainage wound.

His recovery from the operation was uneventful. The daughter cysts and the cyst-wall continued to be discharged with each dressing. On Sept. 21, the cyst wall was curetted with a sharp curette, and on Oct. 8, the patient was discharged in good condition, with a small rubber tube in the sinus. This sinus had closed entirely one month later.

Dr. Simmons reported an echinococcus cyst. The culture taken at the time of operating showed various cocci, mostly streptococci.

After being discharged, the patient was well until June, 1907. He then had a sharp pain in the right side, which on breathing went into the right shoulder. Two days later, he was jaundiced. He gave up work on account of generally poor condition. On June 22, he suddenly felt lame in his back. He became yellow, and had an aching pain in the upper abdomen, which persisted until he entered the hospital. The pain was especially bad between the shoulders and in the right hypochondrium. He entered the hospital on June 27, and had two severe attacks of pain in the right hypochondrium and between the shoulders, similar in all respects to an attack of gallstone colic. With the pain there was an increase in tenderness and rigidity, and his temperature rose to 103°.

Physical examination showed him to be markedly jaundiced. The abdomen was rigid, but not distended. There was a definite tumor on the right, descending to three inches below the costal border. It was very tender, and moved with respiration. On admission, his temperature was 101°, and ranged between this and 103.5°. On July 4, the jaundice was much lighter, his temperature was normal, and the tenderness was less.

The second operation took place July 5, 1907. The old cicatrix was excised. The site of the former cyst was perfectly smooth, and normal appearing, except for the adhesions. In the right hypochondrium, filling the whole flank, was an irregular mass, surrounded by adhesions. This was walled off and the mass broken into. It was found to contain bile-stained, cloudy fluid, and was filled with daughter cysts. The walls of this cavity were irregular, and seemed to be made up of adherent intestines and omentum. The gall bladder was much thickened, and the whole of the left side had disappeared. This also contained daughter cysts and cloudy fluids.

The whole cavity was curetted with the fingers, and packed with gauze. There was considerable shock and inflammatory reaction for a few days, but the patient soon recovered, and left the hospital on July 29, with a small sinus.

Whether this cyst took its origin from the old cyst outside the gall bladder and made its way into it, or originated in the gall bladder and made its way outward, is impossible to say; but judging from the character of the cyst-wall, and the ease with which it was broken into, one would think that the cyst originated in the gall bladder and ruptured into the abdominal cavity.

The patient to-day is in excellent condition, has had no pain since leaving the hospital and there is no evidence of further growth.

There are two points to which I should like to call attention. First, that the patient has not been out of Cambridgeport for sixteen years. This fact, with the marked increase in the number of cases of echinococcus cyst which have entered the hospital in the last two years, and the increase noted in animals by the government officials, would lead one to inquire if echinococcus cysts are not increasing in the United States. I hope to be able to throw some light on this question in a later paper.

Secondly, it will be noted that the culture taken from the cyst at the time of the first operation showed many cocci, and particularly streptococci, to be present. In connection with this, another case which I operated upon this summer is of interest.

The patient was a Greek, who entered the hospital with acute abdominal symptoms, and a mass in the epigastrium connected with the liver. It proved to be an echinococcus cyst, and in spite of the most careful walling off before opening the cyst, and drainage of it with gauze, the patient died of a general peritonitis due to a pure culture of colon bacilli.

One should, therefore, use the greatest care when operating upon these cases, not to soil the peritoneum.

Reports of Societies.

INTERNATIONAL DERMATOLOGICAL CONGRESS.

Sixth International Dermatological Congress, Held at the Academy of Medicine, New York, Sept. 9 to 14, 1907.

(Continued from No. 24, p. 797.)

Second Day, Tuesday, Sept. 10. Morning Session.

The first two hours of the session were devoted to the exhibition of patients and a formal discussion on the same.

Dr. H. Radcliffe-Crocker, of London, Vice-President, in the chair.

THE PATHOLOGY OF THE BROWN-TAIL MOTH DERMATITIS.

Dr. E. E. Tyzzer, of Boston, Mass., in this paper, said the exact date of the introduction of the brown-tail moth into this country was unknown, but it was first noted in large numbers in 1897, in one of the suburbs of Boston. This species had since spread throughout the greater part of New England and had also penetrated adjacent territory. It had been shown that the dermatitis which was produced by these insects was due to very minute, sharp-pointed, barbed hairs, the "nettling hairs" which developed on the caterpillar. The other hairs were harmless. On experimentation with the nettling hairs, it was found that when they were mingled with a drop of blood, a peculiar reaction took place which served as an index to their toxicity. The toxic principle was removed from the hairs by dilute alkalis and by water heated to 60° C., but it was insoluble in other common reagents. It was quite resistant to heat and withstood baking for one hour at 110° C., but was destroyed by baking at 115° C. The nettling hairs after such treatment

no longer gave any reaction when mingled with blood, and produced no irritation when inoculated upon the skin.

TRAUMA AS AN ETIOLOGICAL FACTOR IN SKIN DISEASES.

DR. NEUBERGER, of Nuremberg, Germany, read a paper with this title, in which he emphasized the importance of trauma as an etiological factor in the production of certain skin diseases.

DR. JOSEPH ZEISLER, of Chicago, said that thirty years ago, Kaposi and his school insisted that trauma might act as the focus in the production of various diseases of the skin, and this fact had been pointed out in connection with lichen planus, eczema and psoriasis, and even in syphilis.

DR. A. RAVOGLI, of Cincinnati, said there were a number of diseases of the skin which were apparently the result of trauma, as, for instance, the erythema due to irritation of the skin.

IDIOPATHIC MULTIPLE HEMORRHAGIC SARCOMA (KAPOSI).

DR. M. B. HARTZELL, of Philadelphia, said that in 1872, Kaposi first called attention to an unusual and remarkable affection of the skin characterized by the occurrence of deeply pigmented infiltrated patches and small tumors, situated almost invariably on the extremities, followed after several years by visceral metastases and death, for which he proposed the name idiopathic multiple pigmented sarcoma, a name which he, twenty years later, changed to idiopathic multiple hemorrhagic sarcoma, as being more accurately descriptive of the disease. He regarded the malady as a typical, although special and peculiar, form of round-celled sarcoma, with the occasional occurrence of characteristic spindle cells. Soon after the appearance of Kaposi's paper, other observers began to report similar cases, and the list had steadily, though slowly, grown until the number of recorded cases was now something over one hundred. While the affection seemed to be peculiar to no country nor race, the great majority of cases on record had been reported by European observers, and fully one half of these were from the northern provinces of Italy. The number of cases reported in America was extremely small, and some of these occurred in foreign born. Dr. Hartzell then reported in detail a case of this affection which recently came under his observation.

DR. H. RADCLIFFE-CROCKER, of London, said this disease was rarely met with in England. It was most commonly observed there among the Poles and Galicians.

DR. EDWARD H. SHIELDS, of Cincinnati, referred to a case of this character that he had observed in Kaposi's clinic.

DR. ROLLIN H. STEVENS, of Detroit, mentioned a case very similar to the one reported by Dr. Hartzell, which he had observed in a man, seventy-two years old, a native of Michigan, in whom the disease had developed five years before, after a visit to Denver.

DR. SAMUEL SHERWELL, of Brooklyn, N. Y., said that about 1892 he wrote an article on this subject in which he claimed good results for the use of arsenic in large doses.

MULTIPLE BENIGN CYSTIC EPITHELIOMA. (DEMONSTRATED FROM LANTERN SLIDES.)

DR. M. L. HEIDINGSFELD, of Cincinnati, presented this paper, in which he offered the following conclusions: 1. Multiple benign cystic epithelioma, lymphangioma tuberosum multiplex and adenoma sebaceum were affections which possessed sufficient clinical and pathological variations to render many of the cases of doubtful recognition and classification. 2. These three affections were doubtless of embryonic misplaced tissue origin, and the clinical and pathological variations which were noted in each were sufficiently common to all to give them a common classification, and thereby prevent a somewhat arbitrary, confusing and redundant nomenclature. 3. Some of the clinical and many of the pathological changes had a striking resemblance to those manifested in early malignancy of the skin. 4. It was highly probable that malignancy of the skin, aside from other causal influences, also owed its direct origin to misplaced embryonic tissue.

Dr. Heidingsfeld's paper was discussed by DR. M. B. HARTZELL, of Philadelphia, and DR. JOSEPH GRINDON, of St. Louis.

OBSERVATIONS ON SKIN DISEASES IN THE NEGRO.

DR. HOWARD FOX, of New York, read a paper on this subject in which he gave the following conclusions: 1. In spite of the fact that the negro was more susceptible to disease in general than the white man, and that his mortality was twice as great, he suffered less frequently and less severely from diseases of the skin. 2. The negro skin was decidedly less susceptible to external irritants. 3. The full-blooded negro was almost immune to ivy poisoning. 4. Acne was less common and much less severe in the negro. Rosacea was a rare and very mild affection. Eczema was perhaps not less frequent, though certainly less severe. Psoriasis in the full-blooded negro was very uncommon. 5. Tuberculosis of the skin was not more common in the negro, in spite of the great prevalence in this race of pulmonary and other forms of tuberculosis. 6. Syphilis was certainly more common in the negro than in the white. The acquired form was probably not more virulent, and tertiary forms were not more common. A tendency to the annular syphilide, as well as to keloid, elephantiasis and fibroma deserved to be classed as a racial peculiarity of the negro. 7. The negro was more subject to new growths of connective tissue origin, and less so to those originating in epithelial structures. Cutaneous epithelioma was very rare in the full-blooded negro. 8. The mucous membranes, as well as the skin, were less susceptible to disease. Leucoplakia was seen in the negro with extreme rarity. 9. Many of the rarer forms of skin disease were observed in the negro as well as in the white race. 10. Mulattoes were more susceptible to skin diseases than negroes, being especially prone to chloasma.

DR. ISADORE DYER, of New Orleans, said that in the South, the negro, as a rule, did not apply for treatment for a skin condition, unless it was disfiguring or caused him suffering. The annular syphilide, as seen in the negro, was frequently partly vesicular; there was an arc of the circle which was quite markedly vesicular in type. The observation had been made in New Orleans, that perhaps the only malignant type of syphilis seen there occurred in the negro; only exceptionally in the white.

DR. JOSEPH GRINDON, of St. Louis, said the first question to be answered in regard to the relative frequency of certain skin diseases in the negro was, Who is a negro? To get the facts strictly correct, the investigation should be limited to the pure negroes, on one side, and the pure whites on the other. This, however, would be impracticable, as there was more or less white blood in so many members of the black race.

GANGRENA CUTIS HYSTERICA.

DR. H. P. TOWLE, of Boston, in this paper, limited himself to those cases of gangrene of the skin which were either of artificial or of so-called spontaneous origin. It did not consider the cases of gangrene which occurred in childhood, or which were due to such causes

as bacteria, organic diseases of the nervous system, or to obliterative diseases of the vessels. The paper gave the clinical histories of four cases of multiple gangrene of the skin, three in women and one in a man. While the cases varied somewhat from each other in minor details, they were alike in their essential features. They occurred in patients who were more or less markedly hysterical. Each case had suffered some sort of trauma before the appearance of the first gangrenous lesion. The first manifestation was in the immediate neighborhood of the preceding injury. After varying intervals of freedom, new lesions appeared farther and farther away from the starting-point, as time went on. The affection had existed for months, and in one case for years. The changes in the skin from the time of the first appearance of the lesions until they became gangrenous were very rapid, while on the other hand, healing was very slow. Recurrences never occurred when the patient was under control, and the affection never involved the parts which were not readily accessible. The physical examination showed nothing which would account for the changes in the skin. It was believed the eruptions were all feigned, but the evidence remained purely circumstantial, as none of the patients would confess, and nothing was ever discovered with which the lesions could have been produced.

Dr. H. Radcliffe-Crocker, of London, said that while he fully believed that all of these cases were self-inflicted, very able men who had had such cases under observation for long periods of time had expressed the belief that the lesions were not self-produced, although they were perfectly aware of such a possibility and even probability.

Prof. E. Gaucher, of Paris, France, said the gangrene was a secondary phenomena, caused by infection of a slight abrasion of the cuticle, but hysteria prepared the ground on which the gangrene developed.

Afternoon Session.

Dr. F. J. Shepherd, of Montreal, Vice-President, in the chair.

Theme I. The Etiological Relationship of Organisms Found in the Skin in Exanthemata. Smallpox.

Prof. W. T. Councilman, of Boston, in discussing this subject, said the cause of smallpox was believed to be a parasitic organism having its habitat in the epithelial cells of the specific lesions of the skin. It was first recognized by Guanieri, and named by him cytorrhyctes variolæ. It was described in more detail by Councilman and his co-workers in 1904, and a probable life cycle was established by Calkins. The organism underwent a definite development within the skin, certain forms corresponding with the period of eruption. The same organism up to a certain period of development was found in vaccinia. Certain stages of development were peculiar to smallpox and only found in the lesions of that disease. It was believed that there were probably two cycles of development: (1) an imperfect cycle, probably analogous to the asexual cycle of the coccidia, which was common to both vaccinia and smallpox; (2) a complete cycle, representing a further development of the vaccine cycle, which was only found in smallpox. The virus of smallpox differed from that of vaccinia in its capacity of transmission without contact. The monkey was susceptible to the smallpox virus, and inoculation with smallpox material (contents of pustules) produced a disease with the specific lesions of smallpox and with a complete cycle of the parasite. Inoculation of the rabbit or calf with smallpox material produced a disease comparable to vaccinia, and with the incomplete or vaccine cycle of the organism. The inoculation smallpox of the monkey could be transmitted from animal to animal. The vaccinia produced in the calf or the rabbit, by inoculation of smallpox material was transmitted as vaccinia from animal to animal. Monkeys had been shown to be susceptible to smallpox only by artificial inoculation: it was not possible to infect them by means of exposure. The inoculated disease produced in monkeys had the same period of incubation as variola inoculata in man. In addition to the skin lesions, lesions specific to the disease were also found in the bone marrow and in the testicle. All other lesions of the disease were not specific, and were to be attributed either to the action of toxins or to the action of infectious bacteria, chiefly streptococci. Both vaccinia and smallpox led to active hyperplasia of the lymphoid tissues, with the production of large mononuclear lymphoid cells which passed from the lymph nodes into the blood.

Cytorrhyctes Variolæ: The Organism of Smallpox.

Prof. Gary N. Calkins, of New York, said he would interpret the organism of smallpox as a rhizopod, of which only one phase of the life history was known, namely, the asexual or vegetative phase. This was characterized by development of the chromidium and formation of small reproductive spores (" gemmules ") which repeated the cytoplasmic cycle. The intranuclear forms possibly belonged to the sexual cycle, and it was not improbable that, as Councilman had early suggested, the intranuclear forms might be a different cycle of the organism occurring in variola and not in vaccinia. He would interpret the vesicular forms as either poorly fixed organisms, or as degenerative forms of the organism, the degeneration being produced by the accumulation of toxins found in the breaking-down vesicle. In any event, the intranuclear forms of the organism presented a different history from that of the cytoplasmic forms, and this history remained for some one to work out on well-fixed tissue, or, better still, on the living organism.

The papers of Drs. Councilman and Calkins were discussed by Drs. Walter R. Brinckerhoff, of Honolulu, and Thomas C. Gilchrist, of Baltimore.

The Opsonic Method in Skin Diseases.

Dr. Arthur Whitfield, of London, England, said the term " opsonin " was applied to designate a hypothetical body present in the blood serum. It had not been isolated, but its action had been detected and estimated by Wright and Douglas. The method of opsonic determination consisted of mixing definite volumes of blood serum, bacillary emulsion and living leucocytes under suitable conditions, and afterwards making stained preparations from the mixture to demonstrate the numbers of ingested bacilli. A comparison of various sera by this method gave varying results which might be used for the estimation of the individual resistance to the organism in question. The method had been proved to be accurate within the limits of a 5% to 10% error, which was admitted. The opsonic method might be used for diagnosis, or, in conjunction with the inoculation of bacterial vaccines, for treatment. The diseases of the skin in which the method found a place, were the primary and secondary staphylococcic infections and tuberculosis. The opsonic method in boils was always successful, and was the only form of treatment for general furunculosis that was in the slightest degree reliable. In sycosis the method was a valuable one, but must be continued for long periods in proportion to the duration of the disease, and was best combined with x-ray epilation. In acne, the treatment was uncertain, some results being astonishingly brilliant; others entirely nega-

tive. In septic dermatitis and ulcers, the treatment was of distinct value as an auxiliary. In Bazin's disease the treatment was somewhat uncertain, but it was often of help. In tubercular ulceration it was of great value. In lupus vulgaris, the treatment alone was too slow and uncertain to be recommended. According to Bulloch it was a valuable auxiliary in those patients who relapsed after Finsen's treatment, and the speaker said he had found it of value combined with x-rays.

BACTERIAL INOCULATION IN THE TREATMENT OF SUPPURATIVE AND TUBERCULOUS DISEASES OF THE SKIN AFTER THE METHOD OF WRIGHT.

DR. E. M. VON EBERTS, of Montreal, Canada, after a brief review of the technic of opsonic determinations, gave his results with this method of treatment in acne indurata, sycosis, furunculosis and lupus vulgaris. He stated that in the treatment of tuberculous infections of the skin, the question of autogenous vaccines was at present impracticable, but very encouraging results might be obtained with Koch's new tuberculin (T. R.). Increasing experience showed that the doses originally employed in staphylococcic infections were too large, so that at the present time, instead of 500 millions or more being injected at the initial dose, it had been found advisable to start with 100 or 200 millions, or in a tubercular case, with 1-2,000 to 1-1,800 mgm. of T.R., deciding as to the effect and subsequent dosage by the immunity reaction induced in the individual, as interpreted by the opsonic findings. If the negative phase following inoculation was severe or prolonged, the dose should be diminished. Where, on the other hand, the immunizing response was inadequate, *i.e.*, where the negative phase was suppressed and the positive phase but slight, the dosage should be increased. The objective and subjective symptoms following inoculation were, to a trained observer, almost as valuable guides as the opsonic findings. Experience taught one that exacerbations in the local symptoms were the harbinger or accompaniment of a depressed immunity (negative phase). On the other hand, comparative anemia accompanied the positive phase. This latter phenomenon, no doubt, accounted for the decrease in the subjective symptom of pain, which was invariably admitted in severe furuncular infections. In old lupus cases, the bleaching of the scar was a very striking feature. Constitutional symptoms were rarely met with and should never develop if the dosage is properly adjusted.

BACTERIAL INJECTIONS IN THE TREATMENT OF DISEASES OF THE SKIN.

By DRS. JAY FRANK SCHAMBERG, NATHANIEL GILDERSLEEVE and HARLAN SHOEMAKER, of Philadelphia. In this paper, the authors reported 21 cases treated by bacterial injections. This number included 9 cases of sycosis vulgaris, 3 of furunculosis, 4 of acne, 2 of acne with sebaceous abscesses, 1 of eczema, 1 of psoriasis and 1 of lupus erythematosus. Some of these patients had been under treatment only a short time, and were continuing to make progressive improvement. Of the cases of sycosis vulgaris, 1 was entirely cured; 3 were almost well; 1 was greatly improved; 2 were slightly improved and 2 had not improved. Of the 3 cases of furunculosis one was cured, one was almost cured, and one was improved. Of the four cases of acne two were cured, one was not improved and in 1 the flushing had been relieved. The 2 cases of acne with sebaceous abscesses were decidedly improved. In 1 case of eczema with pyogenic lesions, the latter were cured and the eczema rendered amenable to treatment. The case of psoriasis was temporarily improved. The result in the case of lupus erythematosus was still uncertain. Considering the fact that the majority of these cases were rebellious and of long standing, and that they had resisted approved treatments of all kinds, the results must certainly be regadred as encouraging.

DR. A. RAVOGLI, of Cincinnati, said he could confirm what had been claimed for the opsonic method of treatment in sycosis, and his personal experience with it had been very encouraging.

DR. E. R. LARNED, of Detroit, said that if we could control the size and frequency of the dose by the clinical results, then the opsonic method of treatment would come within the reach of many general practitioners, but if it was necessary in each case to compute the opsonic index, in order to regulate the size of the dosage, and to use autogenic vaccines instead of stock vaccines, then it would be a long time before the problem would be solved.

DR. STAFFORD TAYLOR, of Liverpool, England, said that in some of his cases of sycosis he had derived much benefit from vaccines prepared according to Wright, but the majority required x-ray treatment before a cure resulted.

ERYTHEMA CIRCINATUM BULLOSUM ET HEMORRHAGICUM. AN ERYTHEMATOUS ERUPTION FOLLOWED BY THE FORMATION OF BULLÆ, PETECHIÆ AND DEATH.

DR. WILLIAM T. CORLETT, of Cleveland, Ohio, reported a case of this character. The patient was a boy of twelve, who received a scalp wound from the ball of a Flobert rifle. No serious manifestations followed, and the wound healed in less than a fortnight. At this time, however, the patient complained of acute pains in the joints, notably in the ankles, which were found to be swollen and one was slightly erythematous. This was followed by gyrate and ringed patches of erythema, which extended over the whole body. These at first were well defined, of a pinkish tint with a pinkish fawn-colored central area. Some of the lesions soon assumed a dusky, cyanotic tint which developed into petechiæ. This was followed by the appearance of bullæ, first seen about the neck, and which within a few days involved, more or less, the entire body. The contents of the bullæ, at first transparent, gradually took on a yellowish color. Later many of the lesions became slightly hemorrhagic. The patient's condition began to fail, and finally, three weeks after the injury and a fortnight after the onset of the disease, he died. Cultures from the purulent and hemorrhagic bullæ gave pure streptococci. The autopsy revealed old fibrinous adhesions about the spleen, and the gross appearance of this organ was found more dense than normal. Small hemorrhagic spots were found near the pyloric end of the stomach. At the cardiac extremity, a small area was found denuded of gastric epithelium. There was no evidence that the gunshot wound had any etiologic influence on the disease. The case seemed to demonstrate a connecting link between erythema and purpura.

Dr. Corlett's paper was discussed by DRS. OSCAR T. SCHULTZ, of Cleveland, and EDWARD H. SHIELDS, of Cincinnati.

THE NEED FOR HIGHER REQUIREMENTS IN EXAMINATIONS IN DERMATOLOGY AND SYPHILOLOGY BY MEDICAL COLLEGES AND LICENSING BOARDS.

DR. WILLIAM F. BREAKEY, of Ann Arbor, Mich., said the relative number of patients, clinical and private, suffering from dermal affections, as compared with other special fields of medicine, seemed to furnish a sufficient reason why a general medical education should provide better facilities for the study of dermatology, and of syphilis, in particular, not alone because of its gravity and often unsuspected presence, but also in

view of the awakened public interest in this phase of social life.

Dr. A. Ravogli, of Cincinnati, said that in all of the medical colleges in the State of Ohio, at least sixty-four of the two thousand hours that made up the yearly college curriculum, had to be devoted to dermatology and syphilology. Medical students were already overburdened with work, and he did not think they would ever succeed in compelling the candidates to take a special examination in these branches.

(To be continued.)

Book Reviews.

Physical Diagnosis, with Case Examples of the Inductive Method. By Howard S. Anders, A.M., M.D., Professor of Physical Diagnosis, Medico-Chirurgical College, Philadelphia, etc. New York and London: D. Appleton & Co. 1907.

Why have a new book on Physical Diagnosis? The author's reason is given in the following paragraphs of the preface:

"In my teaching experience it has appeared that the average medical student tends to neglect or misapprehend the intrinsic importance of two things, namely, technic and reason. He is inclined to exhibit a superficial and hasty zeal and endeavor to get at the physical signs somehow, but without methodic and patient procedure and practice; and his mental drift is toward jumping at conclusions from insufficient data and insufficient correlation.

"It is the double-barreled purpose of this book, its dual *raison d'être*, to counteract, as far as textbook influence may (of course less potent than the personal power of the teacher), this deficiency in the student body of our medical colleges."

This tendency certainly exists in the student body, encouraged rather than otherwise by the personal influence of those diagnosticians who, neglectful of method, make short cuts to brilliant diagnoses and thereby fail to emphasize the importance of method. This form of teaching is encouraged by the conditions of out-patient departments in which students work far more rapidly than their mental poise and fundamental preparation justify.

How does the book seek to correct this recognized evil? First, it insists on a necessary preliminary training. "Obviously, the perceptive powers cultivated in the laboratory, the technical skill acquired in handling instruments of precision, and systematic procedures thereby inculcated and ingrained are hardly less than absolutely necessary to modern conditions of intellectual preparedness for successful results in this most objective department of general medical diagnosis." Second, the inductive method is illustrated by cases and their discussion in two chapters, one on pulmonary, the other on cardiac, disease. These two chapters represent the main difference between this book and numerous others on physical diagnosis. They are undoubtedly a valuable addition in showing the student how to study his cases.

The general procedures of physical diagnosis and the interpretation of physical signs, as might be anticipated, do not differ greatly in handling from that in other books. They are quite thoroughly discussed and, on the whole, satisfactorily. Well chosen illustrations, borrowed in the main from other books, help to elucidate the discussion. The book is well made and its pages show careful editing and revision. However, a paragraph of 162 words all in one sentence on page four seems to have escaped attention; here some judicious division would clarify the meaning. Still, there is very little to invite adverse criticism, and Dr. Anders's book can be accepted as a useful addition to the series of smaller works on physical diagnosis, some one of which every student should possess.

A Textbook of Physiological Chemistry. For Students of Medicine and Physicians. By Charles E. Simon, M.D., Professor of Clinical Pathology in the Baltimore Medical College. New third edition. In one octavo volume of 490 pages. Philadelphia and New York: Lea Brothers & Co. 1907.

This third edition differs only slightly from the second edition, such changes having been made as were necessary to bring the volume up to date.

Dr. Simon presents the subject of Physiological Chemistry in an attractive way, taking up the three classes of food-stuffs, their digestion, assimilation, metabolism and excretion, and also the products of various glands and organs. The work is adapted to the use of the student as a laboratory manual and textbook, and to the physician as a book of reference.

Five-Hundred Suggestions, Practical Brevities in Surgical Diagnosis and Treatment. By Walter M. Brickner, B.S., M.D., Chief of Surgical Department, Mt. Sinai Hospital Dispensary, New York; Editor-in-chief, *American Journal of Surgery;* and Eli Moschcowitz, A.B., M.D., Assistant Physician, Mt. Sinai Hospital; Associate Editor *American Journal of Surgery.* Second series, duodecimo. 125 pages. New York: Surgery Publishing Company. 1907.

This little book is worth the dollar charged. In spite of various reviewers' tiresome statements that it is "snappy," and full of useful "diagnostic wrinkles," it is worth owning. It abounds in such aphorisms as occur countless times in the discourse of a clever clinical lecturer: "In seeking a cause for torticollis don't fail to examine the teeth"; "Pyuria without symptoms is suspicious (*sic*) of an early tuberculosis of the urinary tract"; "The silver-fork deformity is by no means necessary to the diagnosis of Colles's fracture"; "Crochet needles are most useful for lifting buried stitches out of a sinus"; "Patients will appreciate the use of black bandages for the scalp — where they are comparatively inconspicuous, and for the hands — where they do not soil," etc., to the limit of the 500.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 12, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

120 BOYLSTON STREET, BOSTON, MASS.

REPORT OF SURGEON-GENERAL, UNITED STATES NAVY.

THE report of the Surgeon-General of the United States Navy for the fiscal year 1907 again brings to attention certain facts of general interest to the medical profession. Among these is the question of recruiting the medical corps to its allotted strength. It appears that in 1905 there were thirty-eight vacancies; in 1906, forty-four; and in 1907, fifty-eight. From this it is apparent that conditions are not improving, and that the authorities are experiencing greater and greater difficulty in finding acceptable recruits for the medical corps. As at present constituted, there are only about 260 medical officers available for the care of over 43,500 officers and men of the navy and marine corps. It is evident that this force is inadequate to the needs of the service, and that criticism may well result. Although much has been done of late to remove causes which have deterred suitable medical men from entering the medical corps of the navy, there are still certain defects to be met. It is admitted that the duties of the naval surgeon are manifold and exacting, and that the men who fill this position should be physicians of sound body and well-equipped minds. Such men are evidently difficult to obtain, as shown by the fact that the number of qualified candidates falls far short of the demand. Of forty-three applicants examined within the last year, only nineteen have qualified for the positions sought, showing on the one hand that a high standard for admission is maintained, and on the other that many men of somewhat inferior qualifications apply.

We have again and again commented on the reluctance of men to enter the medical service, both of the army and navy. In spite of the great overcrowding of the profession in the large cities and the evident opportunities for a career of usefulness and possibly of discovery, recent graduates in medicine remain reluctant to undertake this service, although, as stated above, many of the restrictions have been removed which have hitherto stood in the way of an army or navy career. There should be no reason why the military branches of the government service should not have an excellent medical representation. It remains for those in authority, assisted by Congress and an enlightened attitude in Washington, to remove the remaining defects of the service and to create the necessary enthusiasm among men of promise in the profession.

This report in convincing fashion shows the advantages which a medical man in the navy may enjoy in the way of post-graduate work, hospital service and membership in medical associations. Everything is being done to bring the medical corps of the navy into closer relation with the profession at large, and there is, therefore, no further reason for a man entering the navy to regard himself as isolated from the remainder of the profession. The recently published *Naval Medical Bulletin* should do much toward making the work of medical officers of the navy known and bringing them into touch with the great body of investigators in the medical field.

One of the curious conservatisms, which it is apparently exceedingly difficult to overcome, is the prejudice against the appointment of dentists for service in the navy. For five years consistent and repeated recommendations for legislative authority to employ dentists has failed of enactment. The arguments in favor of their appointment are so apparent and convincing that it would seem that an enlightened Congress must forthwith take favorable action. That this has not been the case is an excellent example of the difficulties under which the medical service of the navy labors in accomplishing reforms. It is to be hoped that a bill, drafted and submitted Sept. 20, will be reported favorably. The question of women nurses has also been most carefully considered by the naval authorities, and recommendations made that such a service be established. Here, again, the necessary legislative authority has not been forthcoming, in spite of what seems to us unanswerable arguments regarding the advisability of establishing such a corps as a part of the medical department of the navy.

If the service is to be made attractive and de-

sirable for promising medical men, it is evident that, so far as possible, the same medical advantages in hospital and on board ship be offered them as are attainable by their colleagues in civil life. It is also apparent that the conservatism which still prevails toward progress in the naval medical corps must give place to a more liberal policy, which makes none but absolutely necessary distinctions between naval and civil medical service. We have no doubt that the situation will finally be adjusted, but while the necessary legislative action is pending, the medical branch of the navy continues to suffer. A reading of the report in its detail is well worth the time of members of the medical profession and of the laity interested in the consistent progress of medicine.

THE CLINICAL TYPES OF CARCINOMA OF THE LARGE INTESTINE.

On account of the variable situation, pathological nature and the relationship that it presents with the various abdominal viscera, carcinoma of the large intestine, if exception is made of the rectum, may affect the most varied clinical aspects. Mickulicz, Boas and Bovis have given various classifications of its symptomatic modalities, but recently Jouffray (Thesis, Lyons, 1907) has again taken up this classification and made it more satisfactory. One must distinguish a type characterized by severe diarrhea. This type, more special to carcinoma of the cecum, is rarely, if ever, followed by symptoms of obstruction. The general condition is greatly affected, while palpation will often allow one to discover a distinct tumor. The evolution of this form is insidious, the patient usually seeking advice on account of indistinct digestive disturbances. He loses flesh, digests badly, and not infrequently, on account of the slow digestion, vomiting arises. Slight constipation appears, and a very careful questioning, and especially a minute palpation after the gut has been emptied by a laxative, should be resorted to in order to discover the presence of a neoplasm, involving the cecum or the ascending colon.

This form, which has been called the digestive type by the above-mentioned author, may also show itself in a more accentuated manner and, under these circumstances, Jouffray has termed it the gastric type. The growth is seated in the transverse colon and involves by compression or by adhesions the pyloric vestibule. Later on, pain is complained of and soon after vomiting occurs. The entire clinical picture is that of a pyloric stenosis. A tumor is discovered and taken for the pylorus, but, nevertheless, a careful analysis of the gastric juices tends to show that this diagnosis is incorrect. Carefully questioning the patient and eliciting the fact that he complains of slight colic will put one in the way of arriving at a correct diagnosis.

The type in which constipation is marked presents an entirely different evolution. An old and increasing constipation opens the drama; it is, in the first place, relieved by laxatives or purgatives, but later it resists these and is only relieved after an attack of obstruction, whose duration is of several days. These attacks of obstruction, which are of short duration and infrequent in the first place, finally become longer in duration, and the patient soon enters into a state of chronic semi-obstruction, characterized by colic and alternating constipation and loose discharges.

At this time the clinical picture becomes completed; a tumor appears, seated over the sigmoid flexure. The end of the evolution suddenly takes place by an acute occlusion; but it must be added that, up to the time of the appearance of this acute occlusion, the clinical evolution of the affection is quite latent, so much so that the discovery of the carcinoma at operation or at autopsy usually completes the diagnosis. This is the type that the author terms the early occlusive.

Occasionally, the physical symptoms are *nil*, while the functional symptoms are reduced to the minimum of intensity, but the general condition alone is seriously involved, thus realizing either the cachectic or anemic type of the disease. Here one is dealing with a latent form, the diagnosis of which is often impossible.

In some instances, it is not the neoplasm which makes its presence evident, but inflammatory phenomena arising in its neighborhood, and infectious complications are produced locally. Soon the evolution of an abscess begins, its seat varying according to the case. One may be dealing with an anterior or iliac abscess, situated in the cecum or sigmoid flexure; an abscess in the hypochondrium arising in the cecum or infrahepatic angle of the colon; a peri-umbilical abscess starting in the transverse colon or a lumbar abscess originating in the angle of the colon.

It can easily be conceived that these various complications may, at the beginning of the process, remain unrecognized, until the time comes when they give rise to a generalized peritonitis. The diagnosis remains impossible, and is only made on the operating table. Being

aware of such symptomatological varieties, as well as their mode of development, it is readily conceived how extreme may be the difficulty of making a diagnosis of carcinoma of the large intestine. Every imaginable mistake is quite possible, and, consequently, one should be cautious, especially when the patient is in the decline of life and at the age when carcinoma is, if not a certainty, at least a probability.

COMMITMENT AND DISCHARGE OF THE INSANE.

THERE are few matters in which the responsibility of the physician is greater than in the commitment of irresponsible persons on the one hand, and their discharge from custody on the other. A recent tragic event, occurring at the Boston State House, in which a discharged inmate of a large insane hospital shot and killed one innocent man and wounded two others, again emphasizes the difficulties under which we labor in properly safeguarding the public from mentally diseased persons. The very proper legal protection thrown about a person subject to commitment to an insane hospital is, we believe, completely adequate in the great majority of cases to protect the abnormal individual from injustice. The responsibility of physicians, however, great as it often is in the process of commitment, merely begins after the suspected person has been safely lodged in a hospital. In many cases, and particularly in those constituting the dangerous class, petitions are too often circulated by misguided friends or relatives that after a reasonable period of residence and apparent restoration to mental health the person be discharged as cured, or at least as no longer a menace to his fellowmen. The difficulties surrounding the hospital authorities in the determination of this question are manifest on the slightest consideration, but are too often overlooked, especially when the public, shocked by an apparently avoidable offence, has its attention drawn to the question. Undoubtedly, experience and judgment of high degree are demanded on the part of the hospital superintendents in the final determination of granting freedom to a previously dangerous man. It is absolutely inevitable that mistakes at times should be made, however closely and conscientiously the past history of the patient may be scrutinized or his possibilities for the future contemplated. It is manifestly desirable that persons of homicidal tendency should be removed from society and kept isolated until all danger is past, and such an instance as that to which we have just alluded merely emphasizes the desirability of all possible precautions. The idea that our hospital authorities are careless or unmindful of their great responsibility, however, is not for a moment to be entertained. On the other hand, considering the number of homicidal persons, both in and out of the asylums, it is matter for congratulation that more mistakes are not made and that more tragedies do not result.

MEDICAL NOTES.

MEXICAN CONGRESS POSTPONED ON ACCOUNT OF DENGUE. — The International Medical Association of Mexico was to have met at Monterey in November for its third annual congress, but it was postponed until Jan. 23 to 25, on account of the prevalence of dengue fever at Monterey. This association combines English-speaking and Spanish-speaking physicians on an equal footing, the programs and summaries being printed in both languages, the speakers using their mother tongue. — *Jour. Am. Med. Asso.*

THE NOBEL PRIZES. — The following prizes under the Nobel foundation were distributed early this month at Stockholm, with the exception of the peace prize, which was awarded in Christiania; the prize for literature was awarded to Rudyard Kipling; physics to Prof. Albert A. Michelson, University of Chicago; medicine to Dr. Laveran, of Paris, as announced last week; chemistry, to Prof. E. Buchner, of the University of Berlin; the peace prize was this year equally divided between Ernesto Todoro Moneta, of Italy, and Louis Renault, of France. At the main award this year, there was no public function, on account of the death of King Oscar. All the recipients were present.

A NEUROLOGICAL HOSPITAL AT BLACKWELL'S ISLAND. — We are requested to announce that at the suggestion of the New York City neurologists, Hon. Robert W. Hebbard, the progressive administrator of public charities, has established the first neurological hospital in America.

The details of hospital organization have just been completed, and a medical board formed. The new hospital is to be known as the Hospital for Nervous Disease of New York City. It is located on Blackwell's Island in detached pavilion wards near the City Home. The present capacity of the hospital is 250 beds. Buildings for the further accommodation of 100 patients are in process of erection. The medical staff will be divided into ten services. Each service will consist of a senior attending physician and

two assistants. The services are to be continuous and permanent. The general hospitals of the city already possess more than a thousand neurological patients awaiting admission to the service. The hospital will be provided with thoroughly equipped laboratories for diagnostic and therapeutic research. Ample facilities for giving special lectures and demonstrations in neurological science will be provided.

The Medical Board is composed of the following: Drs. Francis A. Scratchley, Pearce Bailey, Smith Ely Jelliffe, Joseph Fraenkel, William B. Pritchard, J. Ramsay Hunt, Graeme Hammond, William Leszynsky, L. Pierce Clark, president, and E. L. Hunt, secretary.

The consultants are Drs. C. L. Dana, E. D. Fisher, George W. Jacoby, B. Sachs, Joseph Collins, Frederick Peterson and M. Allen Starr.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Dec. 18, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 56, scarlatina 35, typhoid fever 4, measles 36, tuberculosis 43, smallpox 0.

The death-rate of the reported deaths for the week ending Dec. 18, 1907, was 23.79.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Dec. 14, 1907, was 298, against 231 the corresponding week of last year, showing an decrease of 67 deaths and making the death-rate for the week 25.50. Of this number 151 were males and 147 were females; 293 were white and 5 colored; 182 were born in the United States, 110 in foreign countries and 6 unknown; 59 were of American parentage, 208 of foreign parentage and 31 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 66 cases and 4 deaths; scarlatina, 35 cases and 0 deaths; typhoid fever, 4 cases and 4 deaths; measles, 26 cases and 1 death; tuberculosis, 77 cases and 23 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 53, whooping cough 0, heart disease 30, bronchitis 14 and marasmus 6. There were 13 deaths from violent causes. The number of children who died under one year was 53; the number under five years, 75. The number of persons who died over sixty years of age was 86. The deaths in public institutions were 76.

There were 4 cases and 2 deaths reported from cerebrospinal meningitis during the week.

Lynnfield, Mass., Schools Closed on Account of Measles. — An epidemic of measles has appeared in Lynnfield, Mass., which has led to the closing of the schools by orders of the Board of Health. It is stated that on Dec. 16, nine different grades with an enrollment of two hundred pupils were attended by only six.

Boston Society of Medical Sciences. — At a meeting of the Boston Society of Medical Sciences, held at the Harvard Medical School, Dec. 17, a paper was read by Dr. W. H. Park, of New York, on "The Value of the Opsonic Index in Regard to Treatment." Drs. Timothy Leary, James H. Wright and Cleaveland Floyd were among those who took part in the discussion.

NEW YORK.

Centenarians. — George Olley, believed to be the oldest person in New York State, died at his home at Great Bend, Jefferson County, in the vicinity of Watertown, on Dec. 7, at the advanced age of practically one hundred and ten years. This great age is apparently well authenticated, as the records are preserved of his birth in Stanton, England, on Dec. 25, 1797. He came to Jefferson County in 1826.

Mrs. Annie Friemark, of Brooklyn, N. Y., died at the alleged age of one hundred and one years. She was a native of Russia, and her husband was a lumber dealer of Minsk. She had been in America for only twenty-two years.

Oysters. — In view of the uneasiness which has of late been prevalent in the public mind on account of the supposed danger from oysters, the authoritative statement just made by Dr. William H. Park, of the Health Department's bacteriological laboratory, is reassuring. Dr. Park has found that only one tenth of 1% of cases of typhoid fever can be traced to contaminated shell-fish.

Diphtheria Epidemic on Randall's Island. — The first intimation to the public that there had been an epidemic of diphtheria among the inmates of the House of Refuge on Randall's Island was given when the newspapers announced that in the early hours of Dec. 12, 4 out of 25 of the boys suffering from the disease, who had been removed about three weeks previously to the Willard Parker Hospital for treatment, had made their escape from the hospital.

A Threatening Fire. — There was an exciting time at a fire which occurred on the evening of Dec. 13, in the Huyler chocolate factory, at Eigh-

teenth Street and Irving Place. More than thirty firemen were overcome by smoke, and while a number of them were sent directly to Bellevue Hospital, it was found necessary also to establish an emergency hospital in the annex to the package and storage building of the plant. Here, in a small room on the sixth and uppermost floor, five ambulance surgeons from Bellevue, under the direction of Dr. Reiss of the Fire Department, were working hard for three hours in reviving the overcome firemen. The floor of the improvised hospital was covered six inches with water, and the air was heavy with noxious smoke, but the surgeons remained pluckily at the post of duty and the firemen were constantly revived and sent back to fight the flames. It was the only way in which men could be found to handle the blaze. In one instance, three firemen were found senseless on the floor together, still holding to the line of hose. One of these was carried down to the street and placed in an ambulance by a policeman, but, as the ambulance surgeon was busy in the building, the driver refused to start without him; whereupon, the energetic policeman jumped on the box, and himself drove the ambulance to Bellevue Hospital. At the hospital it was stated that it was well that there had been no delay in the case, as the condition of the man was found so serious that death might result. Among the seven hundred girl employees, who were doing overtime work in preparation for the holiday trade, there was something of a panic, but fortunately they all escaped from the building in safety.

SMALLPOX AT KINGSTON, N. Y. — An outbreak of smallpox has occurred at Kingston, N. Y., 25 cases having developed in the ten days preceding Dec. 14. A characteristic of the epidemic is the mildness of the disease, and in consequence of this, it gained more headway than would otherwise have been the case. In many of the earlier cases, physicians failed to recognize the true nature of the trouble, probably mistaking it for chicken-pox, and, in fact, it was not absolutely established that the disease was smallpox, until State Bacteriologist Curtis arrived and made culture tests. On the other hand, it is stated that, later, a considerable number of cases which had been diagnosed as smallpox were found to be really instances of the less serious disease. The infection is believed to have been brought to Kingston by some negro laborers who recently came from the South to work in the brickyards there.

5. Holt insists that cases of amebic dysentery are to be treated by daily colon irrigations of quinine (1 in 3,000 to 1 in 500). These irrigations are to be given only in the knee-chest position, and preferably by a physician. If the amebæ persist in the stools after a year of colon irrigations, appendicostomy should be performed and the colon flushed out daily with quinine solution. The operation is not serious. There is no difficulty in closing the sinus after the amebæ have disappeared from the stools. The writer reports three cases of amebic dysentery with appendicostomy. The duration of the disease before operation was two, four and nine years. Recovery followed in each case. [R. I. L.]

2. Gordon presents the results of the study of 437 cases of alcoholism. Of these 160 were acute, 277 chronic alcoholism. The cases of acute alcoholism presented good recoveries, and although seen in recurring attacks, no sign of oncoming dementia was observed. Chronic alcoholism, although not absolutely incurable, leads almost inevitably to dementia. However, from his observations, melancholia, mania, paranoia, and general paresis cannot be the product of alcoholism, either acute or chronic.

6. Lydston has employed the intravenous injection of mercury in ten cases of syphilis. A number of these had failed to yield to mercury by mouth or inunction. The results were eminently satisfactory. He used $\frac{1}{4}$ to $\frac{1}{2}$ gr. of the bichloride of mercury (6 to 25 minims of a 2% solution). Daily injections were given until the disease was under control, then the interval was gradually increased. Any prominent and accessible vein may be used. The

writer cautions against keeping on the tourniquet (which is applied to render the vein prominent) after the injection is begun; otherwise cauterization of the vein and phlebitis may occur.

8. Erdman reports 1419 cases of aeropathy (generally known as caisson disease) which occurred during the construction of the East River tunnels in New York. All these patients were affected on coming out of the pressure. The symptoms, which come on usually within an hour, were as a rule pains in extremities, less often vertigo and headache. Paralyses were present in 21 cases, most of which cleared up within a few hours. Two cases persisted, and resulted fatally after several months. The total mortality was less than 1%. Out of the 7 autopsies, free bubbles of gas were found in the blood of 5. In the other 2 cases, autopsy was delayed over eighteen hours after death. From the autopsy findings, animal experimentation, and two clinical cases, in which gas was aspirated from deep tissues, the writer is inclined to the gas emboli theory of the causation of this disease. The treatment is recompression, which gave relief to all but 8% of his cases.

3. Fabyan reports an epidemic of acute pneumonia in a family of ten within ten days. Six of the ten had definite signs of lobar pneumonia. Two others, including the father, who was the first one sick, gave a typical enough history of pneumonia, but had recovered before they were examined. Only one case was fatal. Pneumococci were recovered in this case, both from the blood during life, and from the blood and consolidated lung at autopsy. On careful examination of the home surroundings, no special etiological factors were found to account for this unusual contagiousness of pneumonia.

2. This article is a preliminary report of work on the relationship between avian and human tuberculosis. The authors conclude that the human tubercle bacillus is pathogenic to the pigeon in a very limited degree. It sets up no disease of the intestine or abdominal viscera when introduced with food into the alimentary tract, and when injected into the muscles or subcutaneous tissues, it induces merely a local and glandular disease. The avian tubercle bacillus, as tested from various kinds of birds, is pathogenic to the guinea pig in a very limited degree. The human bacillus is not convertible into the avian by inoculation into the bird, *i. e.*, the bacilli are not identical.

3. McGavin reports four cases in which he used silver filigree in abdominal herniæ, which were considered incurable. He gives the details of the operation in these cases and describes the filigree which he uses. His results were very gratifying in each case. He places the filigree between the peritoneum and the fascia of the rectus muscles. He believes that this is the simplest, quickest and surest means of curing cases of this kind.

4. Western gives a description of his work done in the inoculation department of the London Hospital, in the treatment of bacterial infections by vaccines. He describes the development of this method of treatment, and gives in detail his way of preparing vaccines for inoculation. In tuberculosis, he uses Koch's new tuberculin (T. R.) diluted with .85% solution of sodium chloride, to which is added lysol in the proportion of .25%. His customary initial dose for an adult is now from 1-3000 to 1-2000 of a milligram. He speaks first of treatment of infections with the tubercle bacillus; out of 250 cases dealt with in two years, 200 were cases of tuberculosis in some form. He then tells of the work which he has done in treating tuberculosis affecting the skin and mucous membrane. The difficulty he has had with these is that, while in most tuberculous affections one may rest assured that a vaccine injected subcutaneously will reach the affected part by the blood stream, in cases of tuberculosis of the skin (lupus) there is often so much indurative scar tissue and such a sluggish circulation that one cannot be at all sure that the active agent has reached the spot which it is supposed to benefit. On this account he advises treatment with the Finsen light along with inoculation treatment. He has seen several hitherto intractable cases cleared up by this procedure, although the tendency to relapse seems to be very great. His cases of tuberculous ulceration of subcutaneous tissues and skin, and those of erythema induratum have all done well under inoculation treatment. He has had 30 cases of tuberculous infection of lymphatic glands; 4 of these have shown no improvement; in 8 cases, the glands have entirely cleared up, and in the others there has been a marked improvement. Out of 15 cases of tuberculous disease of the bones, 7 were cured and 5 cases showed marked improvement; 3 showed no improvement. Out of 11 cases of tuberculous disease of the joints and synovial sheaths, 7 are either completely cured or show very great improvement; 2 show no improvement. There were 15 cases of tuberculous disease of the epididymis; of these 6 are cured; 4 are greatly improved and one only has shown no improvement. Twelve cases of acne inoculated with the staphylococcus have shown remarkable improvement. Nine cases of furunculosis have been cured, as well as several cases of intractable carbuncle; 2 cases of cystitis due to the colon bacillus have been greatly benefited; 2 cases of streptococcus endocarditis terminated fatally. On the whole he believes that vaccine treatment at no distant period will rank among the most potent weapons of therapeutics.

5. Statistics show that 80% to 90% of school children have some decayed teeth. Still believes that common digestive disorders of childhood are often dependent upon caries of the teeth, preventing thorough mastication, and that malnutrition is a direct result. Tubercle bacilli have often been demonstrated in carious teeth, and such teeth are undoubtedly one of the causes of tuberculous glands. Whether the glands are infected directly from bacilli present in the carious teeth or not is, perhaps, open to question, but there is no doubt that the presence of suppurating matter in carious teeth may infect the glands, and thereby render them very much less resistant to a tuberculous infection. He believes that decayed teeth are a very real danger to the child whose family history or whose own past history shows a tuberculous tendency. Dental caries is often a cause of habit spasm and epilepsy. Various constitutional headaches are cured by attention to the teeth. He does not believe that candy has such a harmful effect as is usually supposed. In regard to the prophylaxis, he thinks it too late to wait until the child goes to school before giving attention to the teeth, but that this should be done in earliest infancy. He believes that a regular inspection of the teeth of children by a dentist, two or three times a year, will often prevent trouble which at a later period may be very serious.

10. Fairbank has made a study of 140 cases of sarcoma of the jaw, which he has collected from the literature. Microscopical examination of the tumor has been made in every case. The youngest case, one of melanotic sarcoma, was only one month old when the tumor appeared; the oldest, one of myeloma, was seventy-one. Forty per cent of the cases were under twenty years of age. As with sarcoma in other situations, chronic irritation seems to play an important part in the etiology. In only 10 cases out of the 140, however, is mention made of previous caries of the teeth, although this need not alter the fact that teeth are not infrequently the cause of new growth. Out of these 140 cases, 57 were of the myeloid variety and 17 round-celled. The myeloid type were by far the most benign, and at operation required no such radical measures as were needed in the presence of the other more malignant varieties.

2. For some years, Hochhaus has examined the urine for sugar in all cases of cholelithiasis, with only one positive result. In this case, a patient with no previous history of diabetes, during a sudden and severe gallstone colic, showed 3.3% sugar in the urine, which continued from 0.4% to 0.5%, the next five days, and then disappeared altogether. In another case of a man fifty-three years old, with a mild diabetes of about a year's standing and sugar varying from 1% to 5%, after a series of gallstone attacks, the sugar entirely disappeared, and has never returned, although the patient is on an ordinary diet. Glycosuria has been known to subside after other diseases, but this is the first case on record after an attack of gallstones.

4. Conradi, from the examination of over 600 cases of typhoid fever, shows that a large proportion of the cases of contact infection must have occurred during the first week of the primary sickness or earlier, assuming the average period of incubation to be ten days. In 85 cases in which the contact infection was most certain, it occurred in the first week of the disease in 49 cases; in the second, in 16; in the third, in 10; in the fourth, in 5; in the fifth, in 3; and in the sixth and seventh, 1 each. If the incubation is longer than ten days, then infection from the primary case must have occurred before the first symptoms were observed. Conradi is convinced that early contagion plays an important and hitherto disregarded part in the transmission of typhoid fever.

5. Roeder says that a number of instances have been reported in which the resection of peripheral nerve trunks has not been followed by the usual sequelæ. So far, there is no satisfactory explanation of the occurrence. It has been suggested that, as is the case with blood vessels, collaterals may form and take up the function of the divided nerves. In the author's case, two neuromas were removed from the upper arm and shoulder of a young woman. In order to extirpate the tumor, it was necessary to resect a portion of the ulnar nreve, the distal end being grafted into the median nerve trunk. The next day, on removing the dressing, it was found the patient had perfect control of the arm. A year later, another similar, but much larger growth was removed from the pelvis, and in so doing the anterior crural nerve had to be sacrificed. Here again no impairment of function followed.

7. Schäffer recommends that in cases of delayed union after fractures, owing to deficient callus formation, the bone in the neighborhood of the break be subjected to forcible percussion with the ulnar side of one or both hands. Since the idea is to stimulate periostitis and the process of repair, the blows employed must not be more vigorous than those used in massage. The author quotes some successful cases, and claims that this method has the great advantage that immobilization is not required during the treatment, and that the patients do not object to the procedure. 2. Hedinger, following the work of C. Fraenkel, has used intravenous injections of strophanthin in cases of heart disease with broken compensation. He finds that the

results from this method of treatment are very quick and sure. The cases reported which have had chills and temperature after the injections were undoubtedly due to the strophanthin solution being infected. There is no need for this, as the solution can be sterilized. Strophanthin is constant in its action, and does not seem to lose its strength on standing, and cumulative symptoms are never seen. The author believes that 1 mgm. of strophanthin intravenously in the twenty-four hours is much more valuable in broken compensation than the old digitalis treatment.

4. In the observation of a large number of cases of angina pectoris, Schmoll has found that the symptoms may be divided into sensory, motor and vaso-motor manifestations. These are: (*a*) sensory pain, a feeling of impending death, numbness of arm, or arm and leg, etc.; (*b*) motor — irritative or paretic: contraction of the intercostal pectoral or abdominal muscles on the one hand, weakness of the left hand and arm on the other; (*c*) vaso-motor — the left arm or the left half of the body may be blanched during the attack, owing to a contraction of the vessels of the part. Between the attacks these manifestations are less marked, but they are still present, if sought for carefully. Hyperesthesia of the skin over the area of pain during the attack, slight weakness of the part, blanching or cyanosis between the attacks are almost the rule. These symptoms can be traced to one or more spinal segments, usually between the eighth cervical and second dorsal. Schmoll accepts Mackenzie's theory that the irritation proceeding from the heart along the sympathetic to the spinal cord, sets up an irritation there, which in turn is referred to the periphery.

13. Krönig and Grauss have made a large number of observations, on the cadaver and on living subjects, as to the effect of the position of the body, the effect of anesthetic fluids of various specific gravities, and as to the best place for injecting in spinal anesthesia. They find that the position of the body has a great influence on the fluid in the spinal cord, and that it should be controlled during the injection of the anesthetic by an "indicator tube," which they describe at length. The specific gravity and temperature of the injected fluid play a most important part in its absorption. Great care should be exercised in injections with the pelvis raised, as a serious condition may arise if the anesthetic comes in contact with the medulla. They have used both stovain and novocain, the former of which they prefer. When suprarenal extract is used, it must be a fresh preparation. The authors recommend injections of scopolamin-morphin combined with spinal anesthesia for abdominal operations, in order to calm the patient.

5. MEYER, A. *A Method of Opening Peritonsillar Abscesses.*
6. GOLDSCHEIDER. *The Percussion of the Apices of the Lungs.* (Concluded.)

1. Friedberger has found that by the addition of NaCl to serum containing a complement, the stability of the complement is much increased, and it will keep its strength very much longer. The author has no explanation to offer as to the cause of the action of NaCl in this instance.

2. Oestreich and Strauss have shown in an earlier work that in pernicious anemia there is an increase in lymphatic tissue and in lymphocytes in the gastro-intestinal tract. According to the researches of others, this condition is found only in pernicious anemia. A new set of researches seems to point to a relation between the number of lymphocytes in the blood stream and this process in the intestine. So far, it has been impossible to link the symptoms of the disease and these histologic findings together.

3. Hirschfeld reports five cases of polycythemia or plethora vera, with autopsies. In all there was an enormous increase in the amount of blood, and the marrow was found in a hyperactive condition, resembling grossly the marrow of a leukemia. The blood in life usually showed an increase in the number of white cells proportionate to the increase in the number of reds. No blasts were seen in the blood-stream, though always found in greatly increased numbers in the marrow. The author suggests that this condition be called erythemia, and that the condition in which there is an increased red count, but without enlargement of the spleen or changes in the marrow, be classified as erythrocytosis.

6. *GEIGEL, R. *The Tympanitic and Non-tympanitic Percussion Note.*
7. PFEIFFER, W. *A Case of Polycythemia without Splenic Tumor.*

1. In 1903, Lenhartz published an account of 33 cases of staphylomycosis. Since that time 22 additional cases have occurred in the same clinic, and are here reported by Otten. Of the total of 55 cases, 11 were cases of infection with staphylococcus albus, the remainder with staphylococcus aureus. Of the 55 cases only 11, or 20%, were fatal. The portal of entry in these cases was either a furuncle or other lesion of the skin, some lesion of the mucous membranes, osteomyelitis, or in some cases no definite portal of entry was discoverable. In 18 of the 55 cases a furuncle or carbuncle formed the starting point, while in 11 it began with an osteomyelitis. In all of the cases except 6, multiple abscesses resulted. Of the 6 in which there was but a single demonstrable abscess formed, three times it was a paranephritic abscess, twice a brain abscess, and once a liver abscess. In 14 of the cases, an ulcerative endocarditis resulted, six times of the mitral valve, four times of both aortic and mitral valves. In some of the cases diagnosis without blood culture would have been almost impossible.

2. Gerhartz has made a study of the various methods which have been tried to intensify the various sounds listened for in physical examination. Resonators and such methods fail in that they do not increase the intensity of the sounds without changing their character, since they cannot intensify more than a small part of the tones which go to make up the complex sounds which we hear in auscultation of the chest. Consequently, the best that can be accomplished with a stethoscope is a prevention of the dissemination of the sound waves into the surrounding air, and a conduction with as little loss as possible. The parabola construction of the stethoscope bell theoretically offers some advantages in that it focuses parallel sound waves at one point, but in actual use it does not appear to have any very great advantage over the stethoscope bells of ordinary construction. In auscultation, it is to be borne in mind that certain sounds are transmitted poorly by any form of stethoscope, and can be heard best by immediate auscultation, a method which should always be employed in conjunction with the use of the stethoscope.

3. Kappis reports at some length a case of aortic aneurism perforating into the pulmonary artery. In addition, he has collected 32 cases from the literature, 29 of which he has analyzed. In all of these there was evidence of a severe cardiac lesion with sudden onset in most, and very varying objective and subjective symptoms. All but two were in males. The important points in the differential

diagnosis of this condition are: (1) the sudden beginning of severe cardiac symptoms; (2) definite signs of an aortic aneurism (these may be absent since the aneurism most likely to perforate into the pulmonary artery is a small one situated just above the aortic valves); (3) a thrill felt strongest or solely at the base of the heart on the left side; (4) murmur heard in the same region. If the latter is continuous, there is a very strong evidence of a perforation, particularly if the phenomenon has developed during the course of observation of the case. If with signs of aneurism a continuous murmur or a murmur extending from systole to diastole is heard, the condition is very apt to be this one, though a pulmonary aneurism with open ductus arteriosus may produce the same signs.

4. Stursberg has made extensive studies in the relation of systolic and diastolic blood pressure to exercise, in order to determine whether such observations might not be of use in distinguishing organic from functional cardiac lesions. It is found that there are certain limits within which blood pressure and the cardiac output vary under normal conditions, after a graded amount of work. If these same limits are found in cases with cardiac disturbances, it is probable that these disturbances are of a nervous rather than an organic nature. However, there appear to be exceptions in sufficient number to deprive the method of very great use in diagnosing these very important forms of cardiac disease.

5. Two cases of sublimate poisoning and one of oxalic acid poisoning have been studied in relation to the urinary disturbances which result. These cases show first a polyuria of short duration, followed by a suppression of urine, which is gradually replaced by a second period of polyuria which continues until albumin and casts have disappeared from the urine. During the earlier stages of the condition there is an increase of body weight, resulting from the retention of water, though this retention is not accompanied by edema. There are also changes in the secretion of the inorganic salts.

6. Geigel continues the discussion from a preceding paper, of the physical explanation of percussion sounds. In the preceding paper he has explained the metallic percussion note as due to the discontinuous vibration of an elastic body which in vibration produces high over-tones. With a lower grade of discontinuity of vibration, the non-tympanitic note results, whereas the tympanitic note is the result of continuous vibrations started by a percussion blow. [H. A. C.]

12. OPOKIN, A. A. *Pneumotomy in Russia.*

1. Ekehorn reports the case of a patient who had had recurrent renal colic for six years. The attacks had increased in frequency and severity since the last pregnancy. Abdominal palpation revealed an enlarged kidney, situated somewhat lower than normal. Pressure on the abdomen by pushing the kidney upward, relieved the pain. At operation, the only cause of the trouble which could be found, was an accessory artery, entering the kidney just above its lower pole, and about which the ureter was looped. The artery was removed, the patient having no further trouble. Twenty-four similar cases are collected from the literature, emphazing the fact that such anomalies of the renal vessels are not very rare, and that they may cause trouble if the kidney becomes displaced.

2. Kümmell advises the in-lying catheter in cases of incomplete or complete retention of urine without complications. If this does not answer the purpose, after a short time, prostatectomy should be done. The operative risk of prostatectomy, whether by the suprapubic or perineal route, is about the same in his hands. Cancer of the prostate is more common than has been heretofore supposed. A cystoscopic examination should always be made, and if the prostate protrudes more into the bladder than toward the rectum, the suprapubic method should be employed for its removal, whereas if it protrudes most markedly toward the rectum, the perineal route should be chosen. Contra-indications to prostatectomy are advanced arteriosclerosis, diffuse bronchitis, renal insufficiency and entire loss of the contracting power of the bladder. Under conditions such as the above, operation should not be undertaken except for malignancy.

6. After removal of the bladder by shelling it out unopened, having divided the ureters with the cautery, Rovsing brings them both out through the back, through a small incision at the margin of the erector spinæ muscle, about 8 cm. from the middle line. A catheter is inserted into each ureter, and the wounds dressed for a week or so, when the exposed portion of the ureter has dried and shrivelled up, and the remaining portion has become firmly united in its new location. Rovsing then removes the catheter, and controls the flow of urine by an apparatus which consists of a belt containing two silver cups situated over each ureteral orifice, and emptying into a rubber urinal worn below the pubes. He reports the case of a woman of thirty-four years, who has worn a belt for nearly a year, with no discomfort and no leakage. By the above procedure, he feels that the bladder can be removed without danger of contaminating the abdominal cavity, since the operation is done extra-peritoneally; also by bringing the ureters out in the lumbar region, there is not nearly the same danger of renal infection as exists when they are implanted into the rectum or vagina.

7. Nyrop has examined 202 cases of gastric disturbances by the Bourget test meal. He emphasizes the fact that the presence of any portion of this meal remaining in the stomach after twelve hours, means serious disturbance in the function of this organ and calls for a laparotomy in every instance. In 75 of the patients examined, although there was marked evidence of gastric disease, there was no demonstrable retention. From his exhaustive examination of the subject, he concludes that whether the retention be due to malignancy or not, and no matter how slight it may be, it should always be an indication for laparotomy.

8. In the very suggestive article of Friedrich, the present status of lung surgery is reported. The pneumatic cabinet is mentioned as being indispensable. Several instruments are illustrated, and the opinion stated that the technic of such surgery being so little known at present, no one should attempt its application on the human without having had a considerable experience in animal experimentation.

9. Burkhardt finds that the infusion of salt solution up to 2,000 cc. before the administration of chloroform is of great benefit in mitigating the toxic effects of that drug. He feels that it does this by diluting the blood, so that its coefficient of absorption is diminished, while the normal pressure is retained. The beneficial effects are especially noticed in the condition of the pulse during the anesthesia this remaining full and strong, even after prolonged administration of the narcotic. Subsequent nausea, vomiting and headache are also much reduced. The infusion should be given as shortly before the operation as possible. Given after the administration of the chloroform, it has practically no effect.

1. Massabuau, G. *The Histologic Structure and Embryonic Origin of Mixed Tumors of the Salivary Glands.*
2. *Patel, M. *Sigmoiditides and Perisigmoiditides, Simple Inflammatory Affections of the Sigmoid Flexure.*
3. Dieulafé, L., and Herpin, A. *Lesions Connected with the Wisdom Tooth.*
4. *Delore, X., and Chalier, A. *Contribution to Thyroid Surgery.*

2. The term sigmoiditis was first applied by Mayor, ten years ago, to an intrinsic inflammatory process in the sigmoid. Patel now reviews the history of the disease, which he distinguishes as a pathologic entity from specific or secondary conditions such as dysentery, syphilis, tuberculosis or ulcer. Etiologically, chronic constipation, worms, foreign bodies, and general disease are predisposing factors. Anatomically, the most important element is the occasional presence of multiple diverticula, which are starting points of infection analogous to appendicitis. Perforation of one of these may lead to perisigmoiditis, with or without abscess. Various clinical forms are described and discussed.

4. From a personal series of 73 cases, Delore and Chalier make a clinical classification of benign thyroid tumors, exclusive of exophthalmic goiter, into simple goiters and suppurative goiters. The former are chiefly cystic, often with hemorrhagic contents; the latter are generally due to infection of such a cyst, though they may represent a true primary or secondary thyroiditis. Symptoms of thyroid disease may occur without manifest tumor, which in this case may be retrosternal. The authors believe that early operative interference is usually desirable, even before the appearance of functional or pressure disturbances, owing to the liability of benign goiters to undergo malignant degeneration. They find enucleation generally possible, and always preferable to strumectomy or thyroidectomy. They do not think ether contra-indicated or tracheotomy necessary, and have had little trouble from hemorrhage or from injury to the recurrent laryngeal. Suppurative goiters they treat by incision and drainage, after which a secondary strumectomy may be done, but is seldom needful.

Miscellany.

FREE PUBLIC LECTURES ON MEDICAL SUBJECTS.

The Faculty of Medicine of Harvard University offers a course of free public lectures, to be given at the new buildings of the Medical School, Longwood Avenue, Boston, Saturday evenings at 8, and Sunday afternoons at 4, beginning Jan. 4, and ending April 26, 1908. No tickets are required. Following is a list of the lectures and their subjects, with dates:

Jan. 4. Some recent discoveries in the physiology of digestion. (Illustrated by lantern slides and zoetrope demonstrations.) Dr. Walter B. Cannon.

Jan. 5. Human gait. (Illustrated by lantern slides.) Dr. Edward H. Bradford.

Jan. 11. The modern crusade against typhoid fever. Dr. Elliott P. Joslin.

Jan. 12. Common salt. Dr. Lawrence J. Henderson.

Jan. 18. The causes of nervous and mental disease. Dr. Philip Coombs Knapp.

Jan. 19. Fatigue: Its effects and its treatment. Dr. George A. Waterman.

Jan. 25. Nervous disorders of children. Dr. William N. Bullard.

Jan. 26. Nervous breakdown during adolescence and adult life. Dr. James J. Putnam.

Feb. 1. Some of the nervous disorders of adult life, with especial reference to "habits." Dr. Edward W. Taylor.

Feb. 2. Popular fallacies regarding insanity and the treatment of the insane. Dr. Henry R. Stedman.

Feb. 8. Alcoholism and insanity. Dr. Charles P. Bancroft.

Feb. 9. The ear and the telephone. Dr. Clarence J. Blake.

Feb. 15. The interest of the public in surgical progress. Dr. James G. Mumford.

Feb. 16. The sick child. Dr. Thomas Morgan Rotch.

Feb. 22. The causes of disease in infants and children. Dr. Charles Hunter Dunn.

Feb. 23. Rational infant feeding. Dr. John Lovett Morse.

Feb. 29. Syphilis: Its nature and dangers. Dr. James C. White.

March 1. Smallpox and vaccination. Dr. John Hildreth McCollom.

March 7. The problem of the "nervous temperament" in children. Dr. George A. Craigin.

March 8. Florence Nightingale and the beginning of surgical nursing. Dr. J. Bapst Blake.

March 14. Modern methods for the care of the insane. (Illustrated.) Dr. Owen Copp.

March 15. The relation of the hospital to the community. Dr. Abner Post.

March 21. Mental hygiene and the prevention of insanity. Dr. George T. Tuttle.

March 22. Psychic treatment of disease: Its limitations and uses. Dr. Richard C. Cabot.

March 28. What the people should know about tumors. Prospects of cure of malignant disease in the light of our present knowledge. Importance of early co-operation on the part of the laity. Dr. Howard A. Lothrop.

March 29. The development and maintenance of good teeth. Dr. Charles A. Brackett.

April 4. The inflammations due to the commoner pus germs: Their local and general effects. Blood-poisoning. Dr. Charles A. Porter.

April 5. Certain dangerous popular delusions concerning grave surgical diseases. Dr. Maurice H. Richardson.

April 11. Foods in health and disease. Dr. Maurice Vejux Tyrode.

April 12. The development of the microscope. Dr. Harold C. Ernst.

April 18. Some preventable diseases of the skin. Dr. Charles J. White.

April 19. The relation of animal life to human diseases. Dr. Theobald Smith.

April 25. The cocaine evil. Dr. Charles Harrington.

April 26. Tumors. Dr. William T. Councilman.

Also, Laboratory Exhibits in rooms 201 and 202 (Building D):

(1) Paintings and photographs illustrating the changes in so-called chronic rheumatism. Dr. Edward H. Nichols.

(2) An exhibit of certain bacterial and animal parasites, and of organs which show the anatomical changes produced thereby; for example, in typhoid fever, meningitis, diphtheria, anthrax, pneumonia, tuberculosis, dysentery, smallpox, etc. Drs. Frank B. Mallory and S. Burt Wolbach.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED DEC. 4, 1907.

BLUE, RUPERT, passed assistant surgeon. Detailed to attend the meeting of the State Health Officers of California, at Riverside, Dec. 3, 1907.

ROBERTS, NORMAN, assistant surgeon. Granted leave of absence for 7 days from Nov. 22, 1907, under paragraph 191, Service Regulations.

ROBERTS, NORMAN, assistant surgeon. Granted extension leave of absence for 23 days from Nov. 29, 1907. Nov. 30, 1907.

FROST, W. H., assistant surgeon. Granted leave of absence for 1 day, Nov. 24, 1907, under paragraph 210, Service Regulations.

MULLAN, E. H., assistant surgeon. Granted leave of absence for 4 days from Nov. 26, 1907, on account of sickness. Dec. 4, 1907.

DEVALIN, HUGH, assistant surgeon. Granted leave of absence for 1 month from Dec. 16, 1907. Nov. 30, 1907.

DYNAN, N. J., acting assistant surgeon. Granted leave of absence for 7 days from Nov. 30, 1907, under paragraph 210, Service Regulations.

KEATLEY, H. W., acting assistant surgeon. Granted leave of absence for 3 days from Nov. 3, and 5 days from Nov. 13, 1907, under paragraph 210, Service Regulations.

GOODMAN, F. S., pharmacist. On being relieved from the Jamestown Tercentennial Exposition, directed to report to the medical officer in command at Baltimore, Md., for temporary duty and assignment to quarters. Dec. 4, 1907.

HOLSENDORF, B. E., pharmacist. Directed to proceed from San Juan to Mayaguez, Porto Rico, for temporary duty, upon completion of which to rejoin his station. Nov. 29, 1907.

RYDER, L. W., pharmacist. Granted leave of absence for 7 days from Nov. 21, 1907, under paragraph 210, Service Regulations.

APPOINTMENTS.

DR. CHARLES W. HUGHES was appointed an acting assistant surgeon for duty at Baltimore, Md., Nov. 29, 1907.

DR. CHARLES W. NAULTY, Jr., was appointed an acting assistant surgeon for duty at Perth Amboy Quarantine Station, N. J., Nov. 29, 1907.

BOARDS CONVENED.

A board of medical officers was convened to meet at Seattle, Wash., Dec. 2, 1907, for the purpose of making a physical examination of certain detained immigrants. Detail for the Board: Passed Assistant Surgeon L. E. Cofer, Chairman; Passed Assistant Surgeon M. J. White, and Acting Assistant Surgeon F. R. Underwood, Recorder. Nov. 30, 1907.

Boards of medical officers were convened to meet Dec. 6, 1907, for the purpose of making physical examinations of certain officers of the Revenue-Cutter Service to determine their fitness for promotion, as follows:

At San Francisco, Cal., Surgeon H. W. Austin, Chairman, and Passed Assistant Surgeon C. H. Gardner, Recorder.

At Port Townsend, Wash., Passed Assistant Surgeon M. J. White, Chairman, and Acting Assistant Surgeon F. R. Underwood, Recorder.

At Newport News, Va., Assistant Surgeon G. L. Collins, Chairman, and Acting Assistant Surgeon A. C. Jones, Recorder.

At Boston, Mass., Surgeon R. M. Woodward, Chairman, and Assistant Surgeon T. W. Salmon, Recorder.

At Portland, Me., Surgeon P. C. Kalloch, Chairman, and Acting Assistant Surgeon A. F. Stuart, Recorder.

At Mobile, Ala., Surgeon G. M. Guiteras, Chairman, and Acting Assistant Surgeon J. O. Rush, Recorder.

At Detroit, Mich., Surgeon Fairfax Irwin, Chairman, and Assistant Surgeon C. W. Chapin, Recorder.

At Galveston, Tex., Passed Assistant Surgeon G. M. Corput, Chairman, and Acting Assistant Surgeon W. H. Gammon, Recorder.

At Baltimore, Md., Surgeon L. L. Williams, Chairman, and Passed Assistant Surgeon J. T. Burkhalter, Recorder.

SOCIETY NOTICE.

A PROPOSED NEW ENGLAND PEDIATRIC SOCIETY.—The Visiting Staff of the Boston Floating Hospital request all those interested in the formation of a New England Pediatric Society to meet at the Boston Medical Library, 8, The Fenway, Saturday, Jan. 4, 1908, at 8.15 P.M. It is hoped that this movement will excite general interest and that the attendance at the meeting will not be limited to those working along this special line.

JOHN LOVETT MORSE, *Chairman.*
WILLIAM E. FAY.
ARTHUR WILLARD FAIRBANKS.
CHARLES W. TOWNSEND.
HENRY I. BOWDITCH, *Secretary.*

THE ATTITUDE OF THE MEDICAL PROFESSION TOWARD THE PSYCHOTHERAPEUTIC MOVEMENT.*

BY E. W. TAYLOR, M.D., BOSTON.

It must be evident to the most casual observer of medical progress that an extraordinary change has taken place within the last few years regarding the scope of therapeutics. A wider point of view has developed and a more general recognition of the applicability of methods of treatment apart from drugs. The subject which has been selected for discussion this evening offers one of the most striking examples of this expanding point of view, and requires no apology for its presentation at this meeting. It is certainly advisable in this as in other matters of present interest to the medical profession to invite discussion among a body of men who should be representative of the most matured judgment on a subject of much popular misconception. The psychotherapeutic movement within the medical profession has become a definite fact, sure of future development, which can by no possibility be checked, even were such a course desirable. Under these circumstances, it is fitting that the direction which this fundamental movement in therapeutics is to take should be guided by wisdom and encouraged with enthusiasm, tempered by judgment.

It is my purpose to omit any detailed reference to methods or to clinical experience, but rather to draw attention to the broader questions involved in the following propositions: first, the past and present attitude of the medical profession toward mental therapeutics; secondly, the present state of therapeutics in relation to the psycho-therapeutic movement; thirdly, the general attitude of special students of the subject, and, finally, the means by which a knowledge of the movement may best be disseminated.

I. Up to within very recent years, it is not to be questioned that the general attitude of the medical profession toward any method of treatment which appealed primarily to the mind was antagonistic. Those men still within the ranks of the profession, who, through choice or conviction or special training, devoted themselves with zeal to methods of treatment through mental agencies were regarded, and we confess with some reason, as beyond the pale of legitimate practice. The curious and historically interesting growth of mesmerism, hypnotism and allied methods, finally emerging in our present day rational attitude toward the entire subject, has amply demonstrated the deep-seated prejudice which the profession at large has hitherto entertained toward other than physical methods of treatment. The reaction from speculative philosophy and the identification of scientific method with material facts, which was predominant throughout the last century, has stamped itself deeply upon the medical profession, with results which have made possible the advances of the past years. The material aspect of nature has in fact always appealed to the great mass of thinking men, and no doubt will continue to do so at least for many centuries to come. In view of these facts, it is altogether natural that the medical profession should have followed close in the wake of the great scientific revival of the last century, and should in consequence find itself somewhat enthralled at the present time by this salutary but not altogether comprehensive point of view. Many of us have perhaps followed with more or less care the discussion of the modern theories of immunity as propounded by Ehrlich and his students. It is suggestive of the predominant tendency of the medical mind, to which I have referred, that in the elucidation of the theory ideas used to express the subtle interaction of chemical substances find expression in grotesque figures, which by no possibility can express the true facts; and yet to the modern scientific mind such figures constitute a satisfactory interpretation. It is unquestionably true that what is popularly known as the scientific mind finds itself incapable of getting beyond the material world in its interpretation of facts. Medicine has therefore very naturally found itself increasingly unwilling to accept with cordiality ideas and theories which demand other than a physical explanation, with the result that the psychotherapeutic movement which at various stages in the progress of medicine has emerged with more or less vigor, has hitherto for the most part been suppressed and relegated to the region of uncertainties into which the modern scientific spirit was unwilling to probe.

An admirable example of this prevailing feeling throughout the medical profession and a large portion of the more intelligent element in the laity is illustrated by an address which President Eliot of Harvard University delivered at the time of the exercises in commemoration of the opening of the new Harvard Medical School buildings. On that occasion President Eliot chose as the subject of his address, "The Future of Medicine."[1] Throughout his remarks, which traced with great acumen the development of modern scientific medicine and the growth of the laboratory spirit, no mention whatever was made of the possibility of future development in other than purely material directions. The hope of the future, which lies in a clearer comprehension of fundamental mental laws, with research along these lines, together with the great moral and social prophylaxis, which this study seems destined to develop, were absolutely untouched. I speak of this as illustrative not only of President Eliot's point of view, but also as that of the great group of scholars and thinking men of which he stands as a representative. It is likewise clear that from the standpoint of the medical profession at large no deep consciousness of the

* Read before a combined meeting of the New York Neurological Society, the Philadelphia Neurological Society and the Boston Society of Psychiatry and Neurology, at Boston, Nov. 23, 1907.

[1] Eliot: The Future of Medicine. Sanders Theater, Cambridge, Sept. 26, 1906.

possibility of the practical application of mental means to the prophylaxis and treatment of disease has as yet developed. The primary study of mental phenomena is still regarded by the rank and file of the profession with skepticism, although undoubtedly with a growing tolerance. That this is not, however, a universal fact among men of high scientific training is shown, for example, by the stimulating address of Prof. Charles Sedgwick Minot before the American Association for the Advancement of Science, in 1902, of which organization he was then president, on the subject, "The Problem of Consciousness in Its Biological Aspects." [2]

"A frank unbiased study of consciousness must convince every biologist that it is one of the fundamental phenomena of at least animal life, if not, as is quite possible, of all life. Nevertheless, its consideration has barely a place in biological science, although it has long occupied a vast place in philosophy and metaphysics. If this address shall contribute to a clearer appreciation of the necessity of treating consciousness as primarily a problem for biological research to solve, my purpose will be achieved. In an ideal world philosophers and scientists would be identical; in the actual world there are philosophical scientists and scientific philosophers, but in the main the followers of the two disciplines pursue paths which are unfortunately distinct. The philosophical mind is of a type unlike the scientific. The former tries to progress primarily by thought based on the data available, the latter seeks to advance primarily by collecting additional data. The consequence of this difference is that philosophy is dependent upon the progress of science, but we who pursue the scientific way make no greater mistake than to underestimate philosophy. The warning is needed. Data of observation are a treasure and very precious. They are the foundation of our mental wealth, but that wealth consists of the thought into which the data are transmitted. In pleading therefore for an increased observational study of consciousness, we plead not merely for science, but equally for philosophy." Page 277.

"It seems to me inconceivable that the evolution of animals should have taken place as it actually has taken place, unless consciousness is a real factor and dominant. Accordingly, I hold that it actually affects the vital processes. There is, in my opinion, no possibility of advoiding the conclusion that consciousness stands in immediate causal relations with physiological processes. To say this, is to abide by the facts, as at present known to us, and with the facts our conceptions must be made to accord." Page 281.

Professor Minot's plea is significant in relation to the general movement we are considering, since it insists on the recognition of consciousness as a fit subject for biological research. Terminology evidently is of small consequence. What we need as a profession is at the outset simply the conviction that consciousness or mind, as consciousness shows itself in its higher forms, is worthy of our most diligent study, and that by instituting such study we are not proving false to our scientific traditions.

Under the existing conditions of thought on this whole subject it is well to consider in some detail the general attitude of the medical profession toward the psychotherapeutic movement which is now evidently attracting attention from various sources. It is in the first place not to be questioned that the profession at large is becoming interested in the subject. It is, however, evident that a large part of the profession is still in deep ignorance of the real significance of the movement. Many physicians are highly skeptical of the possibility of any practical application of mental means of treatment. Many others are quite willing to listen to the new ideas, but find themselves unable through lack of detailed knowledge to make practical use of them. A comparatively small group finally is deeply interested in the possibilities of a wide application of psychotherapeutic methods, and is doing missionary work at times, possibly with an excess of zeal, toward spreading the gospel. During the past winter I have had the opportunity of speaking before several gatherings of medical men in and about Boston on the general subject. The impression I gained from the discussion which followed these informal talks was that the physicians present recognized in a vague way the possibility of mental influence, but in no instance did I find that they had ever applied modern methods with the same judgment, foresight and knowledge which they would employ in any other therapeutic endeavor. The extraordinary popular and pseudo-scientific interest in matters relating to the possible alleviation of disease by mental means, while forcing general attention, including that of the medical profession, upon the subject, has also done much to antagonize its consideration by men of scientific training. A general opposition to all such methods has too often taken the place of the close and unprejudiced scrutiny which in other matters has been the attitude of the medical profession. There has, up to very recent times, been no general enthusiasm, except among a small body of special students, who for many years have been quietly working at the problem with results which are now becoming manifest.

All this is now changing, and there is no little evidence that a wide departure from the ordinary conservatism of the medical profession may take the place of the indifference of former years. There is unquestionably a certain danger from over-enthusiasm in the present state of the public mind. It is altogether important that no steps should be taken by the leaders in this movement which are likely, on the one hand, to antagonize the conservative elements in the profession itself, and, on the other, to arouse false hopes in the minds of the people at large. Of this I shall have something more to say later. For the present, I wish merely to emphasize the fact that psychotherapy has come to be an accepted method of treatment about which as yet much ignorance prevails in the profession at large, but against which the barriers of prejudice are gradually being broken down.

Reference to the *Index Medicus* shows the

[2] Minot: The Problem of Consciousness in Its Biological Aspects. President's address before the American Association for the Advancement of Science, Pittsburg, July 1, 1902. Proceedings, 1902, li, 265–283.

interesting fact that the word "psychotherapy" as a heading appears for the first time in May, 1906, approximately a year and a half ago. Something over three years before, in January, 1903, the word "suggestion" appears for the first time. The last number of the old series, appearing in 1899, gives no special recognition to either hypnotism or suggestion. It is worthy of note that the term "psychotherapy" has taken the place of suggestion and that hypnotism remains a subject of perennial interest. From May, 1906, when the word "psychotherapy" was first used, to July, 1907, seventy-nine papers and ten books have been catalogued, relating either to hypnotism as such or to the general subject of psychotherapy. It is not to be questioned that this number of references, unless all signs fail, will be greatly increased in the years immediately to come. It is quite unnecessary, before this gathering, to refer in detail to the articles which have appeared within the past few years on the general subject, nor is this the place to discuss the value of various methods. They all have this in common that through primary attention to the mental life of the individual results of significance, both to his mental and physical health, may be secured.

II. The psychotherapeutic movement cannot be properly understood without some reference to the state of therapeutics in general. It is a time of general ferment and increased liberality in therapeutic effort. The recognition of natural agencies in combating disease — fresh air, food, water — has worked a most extraordinary change in our methods of treatment. Pharmacology and drug therapy will continue to hold an important place in the future, but by no means the predominant one which they have hitherto held. There is still, however, in the medical mind a deeply rooted feeling that drugs are the essential basis of all therapeutics. The remarkable agitation which has lately spread over this country regarding the use of proprietary medicines, and so-called nostrums, and the general note of pessimism regarding the failure of our medical students to adequately appreciate the action of drugs and to write prescriptions, is evidence of this widespread feeling. In a recent address before the Section on Pharmacology and Therapeutics of the American Medical Association, Dr. Horatio C. Wood,[3] of Philadelphia, expressed this prevailing attitude of the medical profession in the following words:

"Year after year we gather in medical societies and discuss cases showing unusual symptoms, or points of difficult diagnosis, or problems in pathology; but year after year we fail to say anything about the treatment of the disease. This section itself is an evidence of the desuetude into which the subject of therapeutics has fallen, for despite its vigorous activity in the last few years, it still remains the smallest section affiliated with the American Medical Association, whereas it should be the largest after the general Sections on Medicine and Surgery. In the face of such lack of interest among physicians in the divine art of healing, can we wonder that Eddyism, faith cures, osteopathy and all other kindred schisms flourish so luxuriantly?

"Two very different results have followed this slighting of the subject of therapeutics. On the one hand has arisen a group of nihilists, who because of their own ignorance of the value of medicinal measures, or the means of applying them, stalk up and down the world, proclaiming that all drugs are useless. On the other hand, those who have looked to the leaders of the profession for advice as to curing their patients, being turned away in scorn, have accepted the exalted accounts of those interested in the sale of drugs, and dosed their patients with unspeakable concoctions of the nostrum monger.

"With the former group I confess I have but little patience; the egotistical effrontery of an ignorant workman, who, because he does not know how to use his tools, boldly denounces the tool as worthless, excites disgust for his self-conceit rather than pity for his ignorance. To such practitioners I can only say that if they cannot treat disease they had better abandon the profession of medicine."

It is not in the least likely that physicians will be led back to the use of means which they very probably have found inefficacious by such unconsidered language as this. We need decidedly to broaden our point of view, to appreciate ourselves and to spread the doctrine that therapeutics now-a-days goes beyond the contents of the pharmacopeia, and that the failure to write a complex prescription is one of the least of the shortcomings of the recent medical graduate. A time of readjustment is at hand, and every enlightened physician should do his share toward bringing about this readjustment with equity and wisdom.

Admitting, as we must, the general widening of the therapeutic outlook, it is well to consider whither it may lead. In the first place, it is evident that the physician is coming to occupy a different place, not only in relation to his patient, but also in relation to the community at large. His advice must hereafter cover a much wider field than before the advent of the new methods. His knowledge on many matters, specialist though he may be, must be much broader than that of his predecessors, and his judgment correspondingly developed. Furthermore, it will hardly be said in the future, as it has been in the past, that the physician should not concern himself with the moral welfare of his patient, but merely with his physical condition, even at times to the extent of sacrificing morality to supposed physical needs. In the second place, the physician of the future must look beyond the individual to the social welfare of which that individual forms a part. The advance of therapeutic knowledge has made possible the treatment of groups of persons so that even the peculiarly personal relation between patient and physician will doubtless be modified in the future, though it is to be hoped never lost. I refer especially to the admirable work done by Dr. Richard C. Cabot at the Massachusetts General Hospital in developing a department of social service from a medical standpoint. This movement is significant

[3] Wood: The Place of Pharmacology in Medicine. Chairman's address, Jour. Am. Med. Asso., 1907, xlix, 1411.

of the extraordinary broadening of the therapeutic idea, and reaches out toward the complex social problems which hitherto physicians have merely touched in passing. In the third place, the physician is destined to become more and more intimately concerned with the attitude of mind which we term religion. If it be true, as we are told by Freud and the psycho-analysts in general, that primary emotions must be discovered if the physician is to do his completest work, it is evident that the emotion of religion not only cannot be overlooked but may indeed constitute a most essential object of study. If confession is good for the soul, the physician hereafter must certainly, as never before, assume the rôle of a lay confessor. I wish here, however, merely to draw attention to the apparent fact that the psychotherapeutic movement is doing much toward extending the scope of the physician's work beyond the individual into the social life of the community. However unwelcome this may be to certain ultra-conservative members of the profession, the fact must be met and fairly faced with due deference to the traditions of the profession and at the same time to the manifest claims of progress.

III. What, then, is the attitude of the best special students of the subject toward the possibilities or limitations of psychotherapeutic methods? In general, it is unquestionably one of great optimism. It is very natural that such optimism should prevail, more particularly among those whose experience justifies their claim. The recognition of hysteria as a mental disease, and the striking results which have come from an appreciation of this fact and from study directed in accordance with this idea, has done more than any other one thing to clarify our minds in relation to the practical application of mental methods. Even the pioneer work of Charcot, however, and of his brilliant follower, Janet, has made comparatively slight impression on the general medical mind. The work, nevertheless, thus inaugurated by Charcot's somewhat over-picturesque methods, has proved a source of inspiration to special students, not only in France but in all other countries as well. Its influence is doubtless felt in the later writings of such men as Mitchell, Freud, Dejerine, Janet, Dubois, Sturgis, Dana, Putnam, Walton, Sidis, Prince, Dercum and many others who have made significant contributions to the general subject.

These men, looking at the problem at different angles, may justly be regarded as pioneers in the movement which now shows definite signs of spreading widely throughout the profession. Among these writers we find much difference in the detail of method, but an impressive unanimity in the belief that the whole problem may be approached in a spirit of exact inquiry and by means which are understandable and capable of being practised with greater or less success by any one of ordinary tact and intelligence. It is a matter of extremely small consequence to our general attitude whether Freud's psycho-analytic method on a sexual basis applies to all cases, whether re-education alone is sufficient to accomplish results according to Prince and Dubois, whether substitution as advocated by Putnam or Sidis's hypnoidization is the final key to the situation.[4] It is not open to doubt that each of these methods, in the hands of its special advocates, brings about results. It is furthermore not to be questioned that the same result may be attained by different methods, and that diverse results may be attained by the same method. The one principle at stake for the present is that we have definite methods of some sort which are recognized clearly as legitimate means of treatment. In general, the attitude of special students of the subject conclusively demonstrates the inherent desire for practical methods of procedure, divested of theoretical detail.

It is clear that the work of the past few years has already brought together a mass of facts which are capable of direct application to the practice of medicine. The time has come for at least a preliminary statement of results. In stating these results it should be evident that the same methods must be employed as apply to any other problem in scientific medicine. Facts must be observed and recorded with the utmost care and circumspection and conclusions drawn with just regard to the demands of logic. It is easy to recall in the history of medicine instances in which a precipitate statement of results has led to unfortunate consequences. One recalls particularly in this connection the premature announcement of the supposed therapeutic efficacy of Koch's tuberculin. It is difficult to estimate the harm that was done through the false hopes awakened in the popular mind and so, indirectly, to the cause of medical progress in general by this premature announcement. Tuberculin has since taken its proper place among the useful agents in the treatment of disease, but only after a long period of doubt and uncertainty which might easily have been avoided had the discovery not so soon gained the public ear. In the subject we are now considering this danger is even more manifest. The popular mind is filled with

[4] Among the many papers written recently on the general subject the following not definitely referred to in other parts of this paper are of interest.

ideas regarding the relation of mental processes to the alleviation of disease. Grotesque systems are everywhere about us, and have long held the stage. It is rare to find a person in whatsoever walk of life, or of whatsoever preliminary training, who has not some deep-rooted prejudice regarding the efficiency of mental therapeutics. The public mind is in an absolutely chaotic state regarding the entire question. Under these conditions the medical profession has at last actively taken the field. Misinterpretation of motive is sure to result, and a large proportion of the laity, if not of the medical profession itself, is likely to look upon the movement as a confession of defeat at the hands of the great body of irregular practitioners. It is, therefore, of the utmost importance that, in the prosecution of what seems to me one of the greatest and most beneficent tasks the medical profession has yet undertaken, we proceed with circumspection and with no vestige of precipitancy. It is certainly well to bear in mind that a cause, particularly if widely apprehended by the people at large, may easily be damaged by the excesses of over-enthusiasm. In this problem, beyond all others, the natural conservatism of the medical profession is an asset of the greatest significance. There is not the slightest danger that this awakening of the profession to the significance of the study of mental phenomena in their practical relations will again sink into obscurity, as it has so often in the past, but it behooves those of us who have the interests of the movement particularly at heart to see that no false steps are taken and that the confidence of members of the profession, as well as of the laity, be established at the earliest possible moment.

Wherein does our present attitude give promise of this consummation? Simply, I believe, in the fact that rationality has succeeded speculation, and that method has taken the place of vague generalization. The question, in other words, has now reached a stage when exact scientific methods may be applied to the elucidation of the problem. It is no less essential that we should demonstrate results in such a way as to appeal to the man of science, than that the bacteriologist should prove the capacity of a newly-discovered organism to reproduce a disease under consideration. In either instance, although the tests must be different, the method of procedure should be essentially the same. We must, in other words, rationalize the psychotherapeutic movement if we are to expect to overcome the legitimate skepticism of those whose interests lie in other fields of research. This, I believe, can now be done. The study of the inner life of the individual has reached a point where legitimate generalizations may be made and working hypotheses formulated, which, like any other hypotheses in physical science, must stand or fall under the tests of experience. If the discovery that the existence of a primary emotional state is capable of inducing a life of nervous invalidism be established as a fact, and be capable of repeated verifications, we evidently have a theory which must stand on an equal footing with a theory of immunity, or of opsonic action, or of any other hypothesis, which bids fair to yield practical results. This simple fact, therefore, that we have now established certain laws of mental action which are bearing the rigid tests of experience must be regarded as the essential entering wedge toward a general recognition of the psychotherapeutic movement as a scientific endeavor. Whether we approach the question from the biological aspect, as suggested by Dr. Minot, or from the aspect of a more abstract philosophy is a matter of relatively small significance, provided only we bring to bear upon the subject the same rigid logic which is demanded by other and material forms of research. The immediate aim of special students of the subject should, therefore, be to publish cases illustrative of definite methods; to state facts simply and without recourse to overmuch speculation; and, finally, to maintain an attitude of conservatism in the interpretation of results, such as would be demanded in any problem of physical science.

IV. How, then, may a comprehensive knowledge of the psychotherapeutic movement, as it exists in the medical profession, best be disseminated? It is evident, as I have before pointed out, that the profession is more and more taking the laity into its confidence. The tuberculosis crusade seems to have been the starting point of this movement. The facts regarding tuberculosis are so simple and so easily apprehended by persons of the most ordinary intelligence that the widest possible dissemination of this knowledge was demanded and at once brought results in improved hygiene. So successful, in fact, has been the public exploitation of tuberculosis prophylaxis that an attempt has been made, with more questionable success, to interest the public in other scourges of the human race. Popular lectures on insanity were given last winter at the New York Academy of Medicine, and a largely attended course of public lectures on varied medical topics was inaugurated by the Harvard Medical School, to be repeated this winter. The effect of such lectures is naturally difficult to determine. That they are not universally salutary is my firm conviction. The mere dissemination of knowledge of medical conditions which do not permit of immediate amelioration is a questionable policy. Is it wise to deliver to the public popular lectures on psychotherapy in the present state of the professional and popular mind? I have no desire to be dogmatic on this point, but I doubt it greatly. In such lectures the personal relation between physician and patient is naturally wholly lost, the inevitableness of misinterpretation is so manifestly apparent, and the impossibility of conveying principles of real significance is so small, that for the present I am inclined to think such public lectures should not be given.

A second means of dissemination of knowledge of the psychotherapeutic movement is through the medium of the popular press. Here again the attitude of the medical profession toward

publicity has shown a somewhat striking change within the past few years. Not many years ago an article in a popular journal bearing the name of a practitioner of medicine, if it dealt in the slightest degree with his professional work, was looked upon as a possible breach of professional etiquette. We have certainly progressed beyond this narrow point of view. There is no reason why ascertained facts in medicine should not be given the same publicity as any other matters of knowledge; and we see in the greater liberality of the medical profession in this regard a distinct sign of progress and increased usefulness. The written article differs from the popular lecture in that it presumably is more carefully prepared and presents the results of mature deliberation. Two of our colleagues have recently begun a series of such popular articles. I refer to Dr. G. L. Walton's [5] series of five popular papers on "Worry and Obsession," in *Lippincott's Magazine*, and to Dr. Frederick Peterson's [6] series of letters in *Collier's Weekly* under the general heading, "A Nerve Specialist to his Patients." It is probable that in the hands of men distinguished in the profession such presentations of well-recognized facts from a medical standpoint must, on the whole, be salutary.

In the third place, is it desirable that physicians should ally themselves with movements which primarily lie beyond the scope of the medical profession? I refer in this connection particularly to what is now very generally known as the Emmanuel Church movement in this city. Realizing the shortcomings of practical Christianity in the alleviation of many of the most distressing sufferings of mankind, the rector of this church, himself highly trained in psychology though not in medicine, conceived the idea of popularizing the psychotherapeutic movement on both its medical and religious sides. He was led in a measure to this idea through the great success of a so-called tuberculosis class conducted under the auspices of his church. Although not more than a year old, the reputation of this psychotherapeutic movement has spread widely, not only in this country, but abroad. So far as I am aware, it is the first attempt to combine a church work in which the religious side is given a predominant rôle with the regular practice of medicine. Distinguished physicians have spoken before large audiences at the public meetings given under the auspices of this movement. The attempt has been made to instil into the popular mind useful psychotherapeutic conceptions. The whole movement has excited much comment, with varying opinions as to its wisdom and results. It is not my purpose at this time either to describe the movement in detail or to venture a personal opinion as to its effect on the public welfare. As a church work, conducted by a minister who is also a highly trained psychologist, it is significant of a new and practically useful attitude of the church toward those who may be brought within the scope of its influence. From the medical standpoint, it is far less significant and may hardly be regarded as destined to have a wide influence on the psychotherapeutic movement which it should be our interest and aim to develop within the ranks of the medical profession. In any general and widely-advertised effort of this character it must be remembered that the good accomplished is more widely heralded than the possible harm. All experience has shown that in any such general appeal to the imaginations of untrained minds, psychoneurotic conditions are created as well as allayed. Whether the good counterbalances the harm is not the question at issue; whether all progress arises at the expense of certain classes or individuals in the community, likewise cannot be regarded as an argument in favor of any such movement. As physicians with the best good of psychotherapy at heart, we should not condone the development of possible neuroses on the ground that some or many individuals are helped. It is as much the function of the physician to prevent the growth of modern hysteria in any of its forms as it is to relieve the sufferer who may already be afflicted.

It is a noteworthy fact that students of psychology, irrespective of any medical training, are working in the same practical lines from their particular standpoints. I refer particularly to the work being done by Prof. Hugo Münsterberg of a therapeutic sort in the psychological laboratory at Cambridge, and to the recently established clinic of Prof. Lightner Witmer in Philadelphia. It is perfectly clear that many persons outside of the medical profession feel themselves, and no doubt are, capable of dealing with the psychotherapeutic problem. It is also evident that the medical profession at large must rise to a complete sense of its responsibility in this regard and at least do its share in the work which lies immediately before it, unless this branch of therapeutics is to pass primarily into other hands.

Where, then, should the work of disseminating knowledge really begin if it is to prove effective in the shortest possible time? I have no hesitation whatever in saying that the chief task immediately before the profession is to inform itself and be informed regarding this significant addition to therapeutic methods. It is futile for a few men, enthusiastic in their convictions, to ignore the rank and file of the medical profession in their eagerness to spread abroad the new doctrine. What is primarily required at the present time is the co-operation of all regular practitioners toward the common end. This co-operation is at present wholly lacking, and very naturally so. I venture to say that three fourths of the physicians of this state are quite unaware of the significance of the general psychotherapeutic movement or even of its existence, and this carries with it not the slightest reproach. Popular movements do not appeal to the rank and file of the profession. In fact, they are likely to excite

prejudice and retard progress. There is no more reason why practitioners in remote towns should understand the bearings of this significant movement than that other groups of men should be able forthwith to calculate an opsonic index. The results and the methods of obtaining results should, however, be matters of common knowledge in the one case as in the other, and it is the natural duty of those particularly qualified to spread such knowledge. Papers should be read before medical societies, not composed of special students of the subject, but of those who are quite ignorant of it, or whose knowledge is at best vague and uncertain. In this connection it is a satisfaction to refer to such papers as Barker's,[7] read before the Association of American Physicians last year; of R. C. Cabot's,[8] before the Colorado Medical Society; of Thayer's,[9] before the Louisiana State Medical Society; and of Putnam's, before the Massachusetts Medical Society in 1900. Such opportunities should not be lost, and I have no question that the dissemination of knowledge in this way has the most widespread influence in overcoming inherent prejudices and in promulgating sanity regarding the entire subject.

Even more important, however, than such dissemination of knowledge among practitioners in medicine is the instruction of students. Just here, to my mind, lies the crux of the entire situation. Are our medical schools doing their duty in this regard? Are they in the least recognizing the great responsibility resting upon them toward sending their students into active work equipped with knowledge of the possibilities of psychotherapy? I believe not. So far as I am aware, psychotherapy as a legitimate and essential element in the student's therapeutic training is entirely ignored. We hear much, and particularly from our students, of the lack of teaching in relation to treatment. As the importance of drug therapy has declined, no adequate recognition of other forms of treatment has taken its place, and the student feels himself defrauded of one of the chief objects for which he sought a medical education. The time is certainly ripe for a change in this regard. The medical curriculum must clearly recognize the claims of the wider therapeutic movement, and among these claims none demands greater recognition than psychotherapy. In every modern medical school a course or courses [10] on this subject should be given by properly qualified persons; the word itself should find a place in the catalogue; and the student on graduation should feel that his training had positively included a recognition of mental methods of treatment, and that he can no longer plead lack of instruction, if he later fails in his manifest duty toward his patients in this element of his practical work. It is, therefore, essential that those who already see the vital importance of this therapeutic movement in the profession should do what lies in their power so to impress their convictions upon those in charge of medical education that prescribed work on psychotherapy be introduced into medical curricula. With the rise of the standard of admission to our best medical schools there has been an increasing insistence upon preliminary training. Biology, zoölogy, botany and allied natural sciences are recommended by our leading institutions as a proper if not necessary preparation for the later work in medicine. President Eliot, in the address to which I have already referred, speaks of the physician as a naturalist. After insisting upon the desirability of comparative study he goes on to say:

"Medical students should, therefore, have studied zoölogy and botany before beginning the study of medicine, and should have acquired some skill in the use of the scalpel and the microscope. It is absurd that anybody should begin with the human body the practice of dissection or of surgery; and furthermore, it is wholly irrational that any young man who means to be a physician should not have mastered the elements of biology, chemistry and physics years before he enters a medical school. The mental constitution of the physician is essentially that of the naturalist; and the taste and capacities of the naturalist reveal themselves, and, indeed, demand satisfaction, long before twenty-one years of age, which is a good age for entering a medical school. The Harvard Medical School has derived great advantages from its requirement of a previous degree for admission; but in view of the fact that many young men procure a bachelor's degree without ever having studied any science, the School needs an additional and more specific requirement, namely, a previous knowledge of biology, physics and organic chemistry, and an acquaintance with laboratory methods in all three subjects."

One naturally has not the slightest quarrel with such preliminary biological training, but it is not enough. In the future, if the profession of medicine is to retain its prestige in ministering to all human ills, it is forthwith manifest that our medical students must early be introduced to other departments of thought than those included in what we are accustomed to term the natural sciences. The prevalent idea of the physician as a naturalist will not suffer thereby. In fact, by broadening his training in branches of abstract knowledge, he should become a better and completer naturalist. However this may be, we have reached a stage of progress where the conception of an adequate medical education must be broadened to meet the insistent demands of a wide-spread therapeutic need, manifested by the extraordinary development of this so-called psychotherapeutic movement.

As a result of the foregoing analysis the following matters seem to me important: In our enthusiasm for the development of a highly significant therapeutic advance we should not allow the traditions of the profession to which we belong to be submerged. Our enthusiasm

should not lead to the antagonism of any reasonable member of the profession. In our efforts toward what we regard as progress we should proceed with great deliberation and by recognized logical methods. To this end we should quote cases and exploit methods which have stood the test of experience. We should hesitate in appearing before the public with a detailed expression of our views and theories until we have secured the acquiescence of the conservative members of our own profession. We should not ally ourselves with movements over which we have no immediate control; we can ill afford misinterpretation, especially at the hands of our brother physicians. Our essential aim should be to develop a permanent interest in the psychotherapeutic movement within the ranks of the profession, and to do nothing which can in any way retard this effort. To this end we should urge reasonable but adequate recognition of the claims of psychotherapy as a legitimate and necessary element in medical education. Finally, our one object as members of a liberal profession should be to insist upon the importance of psychotherapeutic methods with an enthusiasm which should only be increased by the legitimate limitations set upon its action. By these means I believe the beneficent results which are destined to result from an acceptance of psychotherapy by the whole medical profession will soonest be attained.

THE USE OF X-RAY EXAMINATIONS IN PULMONARY TUBERCULOSIS.*

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

THE profession is now so much occupied in the study and prevention of pulmonary tuberculosis that it seems opportune to emphasize some of the results of x-ray examinations, which were begun in 1896, in this disease, and to point out again that, notwithstanding the difficulties of the method, they deserve systematic and frequent use, especially because they contribute toward making an early diagnosis and thus help to save lives and prevent the spread of the disease.

Under the term x-ray examination, I include an examination with the fluoroscope and a radiograph, the latter made during full inspiration.[1] Much experience is required to interpret what is seen on the fluorescent screen and in the radiograph, and the best results are obtained from x-ray examinations when they are made by the practitioner who also makes the ordinary physical examination. There is no danger of harm or injury to the patient in carrying out an x-ray examination if it is properly made.

This method may be useful, for example, in:

1. Making an early diagnosis.
2. Making a precautionary examination where there is a possibility that the disease is beginning.
3. Cases simulating pulmonary tuberculosis.
4. Determining the extent of the disease.
5. Determining whether it is diminishing or increasing.
6. The diagnosis of acute miliary tuberculosis and fibroid tuberculosis.
7. Recognizing central tuberculosis.
8. Recognizing sometimes an old tuberculous lesion.
9. Cases in which emphysema or asthma and pulmonary tuberculosis are associated.
10. Making an examination for cavities.

1. X-RAY EXAMINATIONS FOR EARLY DIAGNOSIS.

By the term "early diagnosis" I have in mind an earlier stage of the disease than is usually meant by these words. The x-ray signs of tuberculosis in the early stage are often a restricted excursion of the diaphragm on the affected side, due to the fact that the lung expands less fully than normal; the heart and mediastinal contents drawn by the diseased lung and pushed by the healthy lung somewhat toward the affected side in deep inspiration; the bronchial glands perhaps enlarged, especially in children; and a darkened apex of one lung, although instead of this some other part of the lung may cast the shadow. It is probable that two or more of these signs will be found very early in the disease, and the fact that a group of them may be present at this time adds greater weight to the method. The x-rays show clearly the small heart that is sometimes found in tuberculous patients in the early stages, and this may affect the prognosis unfavorably.

Diaphragm, glands and apices. Importance of quality of light in fluoroscopic examinations. — When one lung is nearly or entirely normal and the other only is affected, the difference in the maximum excursion of the diaphragm on the two sides is often great, but when both lungs are diseased, the difference may be slight. Many so-called early cases are seen when the difference in the excursion of the diaphragm on the two sides is not very marked, which may mean that the x-ray examination has not been made until both lungs have become affected. The position of the diaphragm should be traced on the skin (or on a sheet of glass or celluloid held over the chest), in inspiration and quiet breathing, and then in forced inspiration and forced expiration on both sides, and a record made of these positions for comparison with future examinations. It is well that the source of light should always be opposite the median line on a level with the lower border of the fourth rib, and about twenty-four inches from the fluorescent screen, as by this arrangement, examinations made at different times are comparable.

The glands should be examined with the light going through the body from three directions. To accomplish this object with ease, the patient should be seated in a pivoted chair.[2]

In the early stage of the disease, the practitioner has the opportunity of comparing the

* Presented at the meeting of the Association of American Physicians, held in Washington, May, 1907.

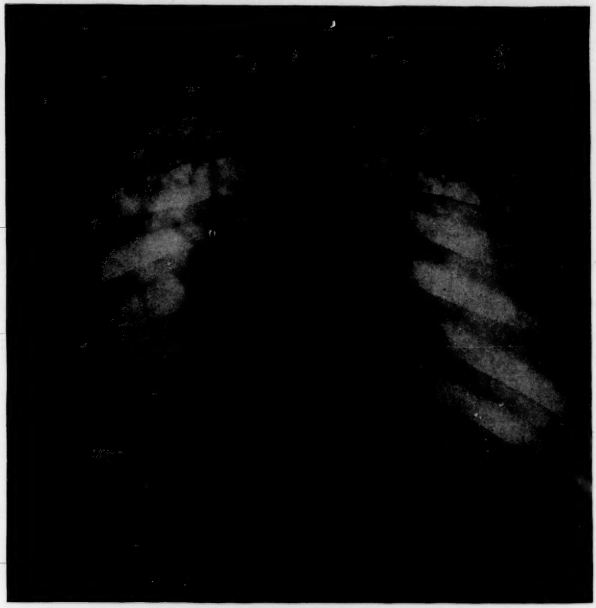

FIG. 1. — Tuberculosis of both apices. The physical signs showed trouble at the right apex only.

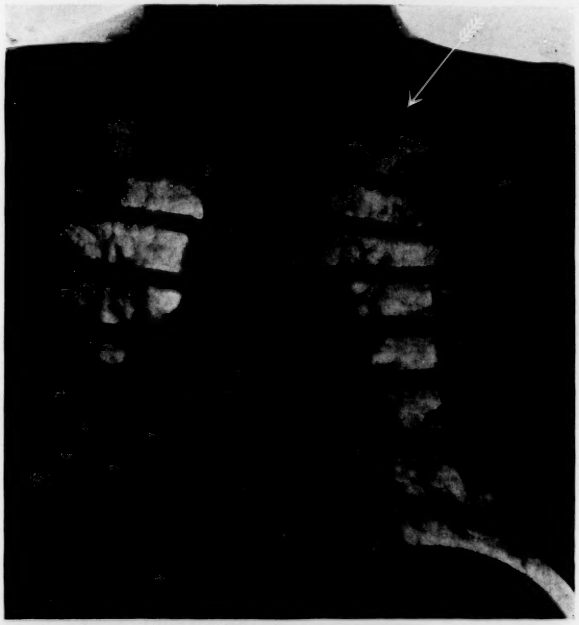

FIG. 2. — Showing small areas of calcification, probably indicating an old tuberculosis.

normal with the abnormal lung. To do this to the best advantage, the patient should take a full breath and the light should be turned down so low that it barely illumines the healthy side. When this very small amount of light is used, a slight increase in density only of the apex of the lung or other parts is necessary to shut out most of it, and, therefore, the practitioner can detect slight differences in density not revealed in any other way. Few practitioners realize the importance of using a small amount of perfectly steady light when examining the chest with the fluoroscope, and the failure to appreciate this fact may prevent them from seeing that the lung is abnormal, until the disease is much more marked. (Hyaline casts cannot be seen in the microscope if there is too much light, as is well known.) By a small amount of light, I mean, as a maximum, in many cases, so little, that five minutes is required to radiograph a hand at a distance of sixteen inches from the tube. This light should be so arranged that it can be readily turned up and down during the examination. Before using the fluoroscope, the eyes should be tested with the spinthariscope.

Radiographs. — To take radiographs of the chest quickly, a strong light is necessary.

The following case illustrates the value of the x-rays in assisting the practitioner to make an early diagnosis: A man, aged about thirty years, who had been overworked, complained to his physician of feeling listless and below par. He took a vacation and returned better, but soon began to feel as before. At this time his physician found no physical signs in his lungs and was in doubt as to whether the cause of his ill-health was tuberculosis or was due to over-anxiety and extra work. About Oct. 1, 1903, he was brought to me for an x-ray examination. He had a pulse of 72, and a temperature of 99°. His physician and I found no physical signs in the lungs at this time. The fluoroscopic examination showed that the excursion of the diaphragm on the right side was 1¾ inches, on the left side 3½ inches, and that the right apex was a little less bright than the left. It seemed wise, with his history and with these x-ray indications of pulmonary tuberculosis, that he should govern his life as if he had this disease. He therefore gave up his work and went away. I expected to see him again in a few weeks, but he did not return until January, 1904. About the middle of this month, a second x-ray examination showed that the excursion of the diaphragm on the right side was 1 inch, instead of 1¾ inches, as in October, 1903, and that the apex of the right lung cast a distinct shadow. The excursion of the diaphragm on the left side was 2¼ inches instead of 3½ inches, as in 1903, which suggested that the left lung was not in as good condition as it had been at the time of the previous examination. This patient went to the Adirondack Cottage Sanitarium, and his examination there in March, 1904, was as follows:

Palpation. — V. F. increased, right base front.

Percussion. — Good note.

Auscultation. — Right, expiration a trifle prolonged; apex, above clavicle. Few fine râles (?), and an occasional rhonchus V. R., normal. Left, fair breathing; V. R., trifle increased to second rib. Few fine râles to second vertebra spine on cough.

Fourteen examinations of his sputum were made and in no case were tubercle bacilli found.

The last examination, on Dec. 2, 1904, showed: Right, breathing better; no râles; no dullness. Left, good note and breathing; no râles.

After leaving the sanitarium tubercle bacilli were found. This patient recovered and has, I am told, been well since that time. Practitioners often suspect pulmonary tuberculosis when they do not feel justified in making this diagnosis. At such a time, x-ray examinations may afford the determining evidence earlier than the usual physical examination.

2. X-RAY EXAMINATION AS A PRECAUTIONARY MEASURE.

The wife of the patient, just mentioned, developed tuberculosis after the recovery of her husband. Precautionary examinations might well have been made in her case.

Such conditions or symptoms as the following may indicate the advisability of x-ray examinations:

(*a*) Patients whose family history suggests the possibility of this disease.

(*b*) In which the patient has been exposed to tuberculosis; for example, because some member of the family or household is or has been ill with this disease.

(*c*) In which the thermometer, as suggested by Trudeau, shows slight increase in temperature during part of the day, or after exercise.

(*d*) Hemoptysis, or loss in weight.

(*e*) Slight but persistent cough, especially in the morning.

(*f*) In which there is tuberculosis in some other portion of the body, and it is a question whether the lungs are or are not affected.

3. CASES WHICH SIMULATE PULMONARY TUBERCULOSIS.

X-ray examinations are used to advantage in these cases, as illustrated by the following instance: The diagnosis made by three physicians was pulmonary tuberculosis. The friends of the patient had presented him with a purse to enable him to go to Colorado. Before attempting to start, he came to the Boston City Hospital to ascertain how extensive the disease was. His record is as follows:

David G., aged thirty-nine years. Admitted to Boston City Hospital, Sept. 26, 1898. Pleurisy one year ago; cough for two years. Caught cold six days ago; chill, knife-like pain in left side.

Sept. 26. On admission, pleuritic pain in left side. Temperature 99.2°; pulse, 80; respiration, 23.

Sept. 29. Right apex front and behind prolonged expiration; slightly higher pitched than on the other side. Vocal resonance slightly increased, and marked whispered bronchophony. No râles

over this area, and no change in percussion. In right base behind, numerous medium and moist râles heard best with inspiration, and without change in percussion and voice sounds. No tubercle bacilli in sputum in two examinations.

Oct. 6. Patient shows some improvement. Cough nearly gone. Chief symptom is weakness and pallor. Desired to go home.

Oct. 20. Returned. Cough returned; whitish expectoration; some pain in side; appetite poor. Has had chills for three days. Temperature, 99.3°; pulse, 80; respiration, 23.

Lungs: Slight dulness at right apex in front and behind, with increase in vocal fremitus and resonance, and considerable whispered bronchophony; no râles. Question of malaria; no plasmodia found; no temperature.

Oct. 25. Feels stronger; no chills; no temperature. Coughs very little.

Nov. 5. Given 5 mgm. tuberculin.

Nov. 6, A. M. Temperature 102.5°. This temperature thought afterward to have been due to malaria, not to the tuberculin, as plasmodia were found later.

Nov. 13. Tuberculin 5 mgm. again given; no reaction.

Nov. 16. In right back tactile fremitus increased and percussion slightly duller than normal over whole of right back. On left, from apex to third rib in front, expiration is harsh and prolonged, and fremitus increased.

I made an x-ray examination of his chest and found that his lungs were clear and that the excursion of the diaphragm on the left side was 2⅜ inches, and on the right side, 2¾ inches. He deferred his trip to Colorado by my advice, and eventually gave it up altogether. I have seen him at intervals since that time and he did not develop tuberculosis. He died of cancer of the throat, eight years later, in September, 1906, at the Massachusetts General Hospital, after operation.

I think the diagnosis of early pulmonary tuberculosis should be carefully reconsidered if a properly made x-ray examination does not reveal an abnormal condition of the lungs.

4. X-RAY EXAMINATIONS IN DETERMINING THE EXTENT OF THE DISEASE.

In deciding on the best course for a patient to pursue, who has already well-marked signs of the disease, not only the condition of the patient, but the extent of the disease should be known as accurately as possible. The x-rays in many cases reveal more exactly the extent and distribution of the disease than any other method. They frequently show that both lungs are involved, when, without the use of this method, only one lung would be suspected. In other words, the x-rays indicate early the advent of the disease in the second lung as well as in the first (in such a case the advantage of comparing the normal with the abnormal lung is lost). Before admitting patients to sanatoriums as early cases of tuberculosis, they should be examined by the x-rays, for if this is not done they will sometimes be sent there with the mistaken idea that they are in an early stage of the disease.

5. X-RAY EXAMINATIONS IN DETERMINING THE DEVELOPMENT OF THE DISEASE, WHETHER IT IS DIMINISHING OR PROGRESSING.

Another use of the x-ray examination is to show with what rapidity the disease is progressing. For example, let me take the case of a patient, one of whose lungs seemed to be involved, but not to any considerable extent. The first x-ray examination showed that the disease was more extensive than the physical examination indicated, and each subsequent examination, made at intervals of two or three weeks, demonstrated that it was rapidly extending. This progress of the disease was indicated only by the x-ray examination. The physician of the patient had planned to send him to Colorado. I advised and urged that the plan be given up. He started, however, and after a fatiguing journey, resting here and there on the way, arrived in Colorado, but left for home a few days later and died ten days after reaching home. It is hardly necessary to dwell on the suffering which this man must have endured in the two long journeys, which the x-ray examinations had shown would probably be worse than useless at that time.

7. CENTRAL TUBERCULOSIS.

It is well known that central pneumonias may be readily seen by means of an x-ray examination before they extend sufficiently near to the surface of the lung to be recognized by a physical examination. The dense portion of the lung casts a shadow on the screen whether it is central or superficial. In like manner the increase in density, obtaining in pulmonary tuberculosis, is revealed by the x-rays even when deep seated.

8. OLD LESIONS.

Where we find indications of calcification, as illustrated by the accompanying figure, it should suggest an old pulmonary lesion.

9. CASES IN WHICH EMPHYSEMA OR ASTHMA AND PULMONARY TUBERCULOSIS ARE ASSOCIATED.

An x-ray examination is useful in recognizing pulmonary tuberculosis when other conditions are present which complicate the case. For example, when a patient is suffering from emphysema of the lung and pulmonary tuberculosis, the emphysema masks the ordinary physical signs of tuberculosis, but the density of the lungs is even more clearly revealed than usual, when the chest is examined by the x-rays, if the patient is also suffering from emphysema.

USE OF THE X-RAYS IN SANTORIA.

It is hardly necessary to point out, from what I have already said, that the x-rays would also assist in determining the favorable course of the disease and could be of service in sanatoria and other places where there are many patients who should have every advantage which the best

methods of examination can afford. The importance of these examinations at sanatoria has been shown among others by Brook and Green.[3] They say:

"The conclusions we arrive at are formed from the study of a large number of cases in all stages of the disease:

"1. In no single case, where the physical signs have pointed to disease, have the x-rays failed to detect the mischief.

"2. In some cases where physical signs have been absent the rays have shown a deposit in the lungs, and in these cases physical signs have subsequently been detected.

"3. That the early diagnosis is certainly helped.

"4. That the extent of the disease, in many cases, is shown to be greater than the physician thinks.

"5. That the progress and results of treatment can be watched with great accuracy."

X-ray examinations are valuable for life insurance companies.

X-ray examinations are difficult to carry out. Proper precautions should be taken to protect the practitioner as well as the patient.

Practitioners who are devoting themselves to diseases of the chest should have a suitable x-ray apparatus, just as an ophthalmologist has an ophthalmoscope, but the task of the latter is far lighter than that of the physician who desires to make a complete examination of the chest.

Practitioners who have had experience with x-ray examinations appreciate that, as a rule, they give a more definite and correct picture of conditions in the chest than any other method. This information is valuable not only in assisting the practitioner to make an early diagnosis, but also in later stages of the disease. There is now, according to some observers, an average delay of perhaps a year or more after the first symptoms of tuberculosis are observed, before the diagnosis is made. X-ray examinations assist in shortening this delay and thus help to lengthen the lives of tuberculous patients and diminish the spread of the disease. When patients realize that early diagnosis usually means recovery in a comparatively short time, and that a delayed diagnosis may exclude recovery, they will, I believe, seek x-ray examinations.

THE RESULTS OF THE CHEMICAL INVESTIGATION OF TUMORS.

BY S. P. BEEBE, NEW YORK.

During the last ten years the public interest in problems of scientific medicine has increased in large degree and many laboratories have been founded for the scientific investigation of particular pathological conditions. Nearly all of the special laboratories and funds for the study of malignant growths have had their origin during this period. You are all familiar with the remarkable advances that have been made in the application of the exact methods of chemistry to problems of biology during this same period. We need scarcely add, therefore, that our knowledge of the chemistry of neoplasms is a very modern product. However, only a small portion of the abundant tumor literature of the last decade has been devoted to chemical subjects. Such contributions as have appeared have aroused very little discussion because of their fragmentary character; and because they have formed no essential premise in the arguments regarding the nature of neoplasms, which are the chief contribution of the pathologist. The chemist has not been familiar with the past history of the tumor discussion, nor its present condition, and the pathologist has not been fully acquainted with the ways of chemistry and its language. The two are therefore just beginning to appreciate the necessity for mutual co-operation, and we find that the results of the chemist are being used more and more as a basis for the hypotheses of the pathologist. It is, I believe, a good thing that such a condition of affairs is coming, for the findings of chemistry are those of an exact science, and the personal equation is likely to cause a larger error in drawing conclusions from and properly interpreting the data of clinical and histological observations than can be admitted in an experiment where the various factors are subject to the control of the chemical balance.

In presenting the results of the chemical investigation of tumors, I shall not attempt to give a résumé of all the analyses that have been made, but I shall select those which I think are of most interest, and it is convenient to group these somewhat in the order of their complexity.

I. THE INORGANIC CONSTITUENTS OF TUMORS.

Few systematic analyses of tumors for the important inorganic elements are reported in the literature, and yet there is an abundant physiological evidence that such elements are vital factors in the proper functioning of various tissues. Four years ago, I analyzed a number of these tumors in various stages of growth and degeneration for the elements sulphur, iron, phosphorus, calcium, potassium and sodium.[1] No conclusions of great value can be drawn from these analyses, but an interesting suggestion was found in the fact that the actively growing tumors contained a much larger amount of potassium and sodium, and a much smaller amount of calcium than was found in the old, necrotic tumors. The later work of Clowes and Frisbie,[2] who analyzed a series of transplantable mouse carcinoma in various stages of their growth, has confirmed these findings.

The work of Loeb,[3] Howell, Matthews and their students, during the last few years, has revolutionized our ideas regarding many fundamental physiological processes, and has demonstrated in how great a degree vital activities are dependent upon the physico-chemical environment — an environment profoundly influenced by the nature and amount of the inorganic salts.

We know, for example, that the secreting cells

[3] A Preliminary Note on the Use of the Röntgen Rays as an Aid to the Early Diagnosis of Pulmonary Tuberculosis. Quart. Med. Jour., Sheffield, 1902, 1903, xi, 268–272.

of the intestine are stimulated to remarkable activity by the presence of potassium, and that this activity is inhibited by the exhibition of calcium. It may be that in some way a similar relation holds true for the tumor cell. It is certain that the varying quantities of these elements found in the different stages of the tumor growth are not accidental factors, but we cannot, however, on the basis of our present knowledge, say precisely what are the mechanisms concerned.

The studies of the distribution of iron, phosphorus and potassium, as carried out by microchemical reaction, have not shown any peculiarities that differentiate tumors from normal tissues. Dr. Tracy [4] has carried out a series of experiments along these lines in our laboratory, and has found that the methods are unsatisfactory, but as far as results apply, they indicate that these elements are found in tumors in similar distribution and amounts, as in any active normal tissue.

II. PROTEIDS OF TUMORS.

A considerable amount of work has been done during the last five years in comparing the character of the proteids found in malignant growths with those found in normal tissues. It seems reasonable to believe that a tissue which has such a marked peculiarity of unreasonable growth as a tumor must have some basis for this behavior in its chemical structure. There are a number of observations which indicate that a carcinoma retains some of the physiological activity of the tissue from which it developed. One need only cite the presence of iodine in thyroid tumors or the well known fact that cancers of the adrenal do not cause Addison's disease in support of this statement. One of the first observations of the character of proteids in tumors is reported by Petry [5] who salted out the nucleo-proteid, globulin and albumin from a saline extract of five carcinomas and compared the quantities found with those found in extracts of the surrounding normal tissues. His results show that the tumors were relatively richer in nucleo-proteid, and poorer in globulin and albumin than control normal tissues from which the growths had originated. These conclusions, however, are based on only two complete analyses properly controlled, so that his findings are only a suggestion. A very similar piece of work, reported by Wolff,[6] has been widely quoted as evidence that the proteids of neoplasms have a characteristic structure. Wolff separated the euglobulin, pseudo-globulin and albumin from the expressed juice of a number of tumors, and found results practically in agreement with those previously reported by Petry; but he, likewise, found that these proteids have the same precipitation limits with ammonium sulphate as those of normal tissues, and his own conclusion is that the character of the proteids is identical with that of normal tissues, and it is only the quantitative distribution of these that differentiates the tumor from the physiological tissue.

During the last year, we have carried out somewhat similar experiments upon a much larger number of specimens than either of these other men, and our conclusions are, with some minor exceptions, in accord with those of Petry and Wolff, namely, a larger amount of nucleo-proteid, less globulin, more albumin and much more non-coagulable nitrogen than is found in normal tissues. Such experiments are not suited to determine the character of the proteid, but only give information as to the distribution of the proteid in its various forms, and thus they throw some light on the pathological processes in the tissue but are of no value in differentiating between proteids which must be so closely related.

The large quantity of nucleo-proteid found in a tumor corresponds with the histological structure, and a large quantity of non-coagulable nitrogen is the logical sequence of the autolytic processes of such tissues. The distribution of nitrogen in the tumor extract varies within wide limits, depending upon the state of the tissue as regards necrosis and also depending upon the method of preparing the extract.

It is well known that many tumors suffer an impairment and, in some instances, a complete stoppage of the circulation of blood and lymph in the central portions of the growth. As a consequence of this impaired circulation, necrotic processes ensue and conditions are favorable to autolysis with an accumulation of autolytic products. It is known that aseptic autolysis at body temperature proceeds very much faster than antiseptic autolysis, where the enzymes are exposed to the injurious action of some bacterial poison, such as chloroform, toluol or sodium fluoride. In the central necrotic portions of a large tumor, there is a mass of tissue at the body temperature, free from bacteria, rich in enzymes, free of the inhibiting influences of the circulating blood and uninjured by chemical antiseptics. Such conditions are almost ideal for autolytic activity, and we find evidences that such action takes place in the amido-acids found in the extracts of such tumors. I have already published analyses of extracts from a series of sterile tumors, obtained fresh from operation, in which I found the products characteristic of cleavage by digestive enzymes, a striking instance being the finding of considerable amounts of glycocollnin, a carcinoma growing in the broad ligament. Autolysis is a process of gradual hydrolysis and with its progress a proteid has less and less of a colloid character, and consequently requires a higher concentration of salts to precipitate it, and a larger percentage of it has progressed so far in this degradation, that it is not precipitated by salts, nor can it be coagulated by heat. Therefore, the distribution of the proteid in the less colloidal state merely indicates that the biological processes of tumors are somewhat different from those of normal tissues.

To differentiate sharply between the essential characters of two proteids, a different means must be employed. By ultimate analysis or by precipitation behavior, we would not be able to differentiate between the serum globulin from two different species of closely related animals.

Two methods are available to distinguish between closely related proteids. We may use the biochemical method involved in the precipitin test, or we may completely disintegrate the proteid into its crystalline decomposition products, and separate these quantitatively into various fractions, — a method which requires a large amount of tissue, a corresponding quantity of skill and patience, — and except under very favorable conditions, the results will not be satisfactory. I have carried out a considerable number of tests by the first method, using the nucleoproteid of the tumors to develop the antiserum with which the precipitin tests have been made, and have been able to distinguish by such means between the tumor proteid and a widely different range of normal proteid, for instance, between the proteid of a lympho-sarcoma and the proteid of the liver, spleen, pancreas, thyroid, but I could not distinguish by this means between the proteid of the lympho-sarcoma and that obtained from an enlarged spleen, from a case of leukemia.

Bergell [7] and Dorpinghaus have reported the analyses of a mixture of tumors by the second method outlined above and claim to have found differences which justify them in concluding that tumor proteids have a characteristic grouping of amino-acids, the diamino-acids being much increased, and the monamino acids decreased. These results are in direct contradiction to those of Neuberg [8] and Petry,[9] as well as my own, so that no conclusions on the point of issue can be drawn.

The justification of the methods of comparison between tumors and healthy tissues is more apparent than real. A tumor is often composed almost entirely of a single kind of cell, whereas a normal organ is a composite structure, made up of a great variety of separate components which may reasonably be supposed to differ quite widely from one another. For instance, a comparison between the chemical structure of a primary carcinoma of the liver, starting in the gall ducts with normal liver tissue, is hardly justifiable. The cells lining the gall ducts are the parent cells of the mass of the tumor, and these probably have a different chemical structure from the large mass of liver cells which make up the bulk of the normal organ. It is obviously impossible to separate out that particular group of cells from a normal organ in sufficient bulk to make a quantitative chemical examination, and yet it is these cells which should be compared with the cells of the neoplasm. I am inclined to believe that the term anaplasia may apply to the chemical, as well as to the histological, structure of a malignant cell, but the work thus far reported is not satisfactory proof of such a relation.

In some instances there has been a comparison of the chemical composition of the primary growth with that of the secondary growths in some distant organ. Bang examined, with negative results, five fibro-sarcomas for a peculiar proteid, nucleo-histone, found only in lymphatic tissues. In the sixth case, he examined a growth in the inguinal lymph node, secondary from a sarcoma of the testis, extirpated about one year previously. Here he found a body having a phosphorus content of 5.18%, and the reactions of the nucleo-histone normally found in lymph glands.

Unfortunately, the primary growth was not examined chemically, but Bang [10] believes that the tissue which he used had its origin in cells directly transferred from the growth in the testis, and that chemically, therefore, the primary growth was similar to the metastatic growth in the lymph-gland. Nucleo-histone is not a normal constituent of the mammalian testes, and reasoning from these premises, Bang concludes that the primary growth had its origin in an embryonic lymphatic cell group retained in the testes. The conclusion is an argument for Cohnheim's theory.

From analyses of fourteen malignant growths, including epithelioma, sarcoma and carcinoma, after much the same method that Bang has used, I concluded [11] that primary epithelial growths do not contain a nucleo-histone, while the secondary growths found in the lymph-nodes invariably yielded nucleo-histone. I cannot agree, therefore, with Bang's conclusion. From the abundance of the nucleo-histone in the secondary growths in the lymph-glands, I was led to believe that, chemically at least, the metastases are not in all respects similar to the primary growth, and it appears as though the cells lodging in the lymph-nodes had been influenced to some extent by their environment.

Neuberg [12] has attempted to draw somewhat similar conclusions from the findings in regard to the pentose of a carcinoma of the liver, primary in the stomach. In our laboratory we [13] have analyzed a series of tumors and normal tissues for the content of pentose, and if selected instances are chosen, we may conclude that the pentose content of the secondary growths is similar to that of the primary, but our results as a whole show no consistent relation of pentose to the origin, malignancy or degeneration of the tumors. It seems to me very probable that the peculiar activity of a tumor cell is a function of its chemical structure; but the chemical studies which have been made of the proteids of tumors are quite inconclusive and show no undoubted differences from normal tissues. The analyses thus far are mere suggestions and have demonstrated only that the differences, if they do exist, are not profound ones.

Blumenthal and Wolff have reported a few experiments which have been quoted as evidence that tumors are differentiated from normal tissues by their more complete and ready digestion by trypsin as compared with pepsin. (It is interesting to note that Blumenthal now makes the claim that his experiments are the scientific basis for the trypsin treatment of tumors.) The experiments are conflicting, however, as in three cases out of five he found peptic digestion more completely digested the tumors. From our common knowledge of digestion, we should expect trypsin to digest the tumor more completely than pepsin, because the tumor proteid is largely nucleo-pro-

teid and peptic digestion necessarily leaves the large content of nuclein undissolved, while tryptic digestion readily dissolves the whole tumor tissue. Such experiments, to be of any value, must be carried out upon isolated, purified proteids from the two sources, and not upon a heterogeneous indefinite mixture of various kinds of proteid and proteid cleavage products.

III. TOXINS IN TUMORS.

Many investigators have endeavored to demonstrate a specific toxic substance for the malignant cell, but thus far no definite toxin has been isolated and studied. I shall not refer to the numerous experiments in which toxic substances are reported in the urine of cancerous patients, because their origin, if they are present, is doubtful and the results have not been properly controlled. We have observed in the course of immunization experiments that extracts of tumors, and particularly necrotic tumors have a much greater toxic effect upon the animal inoculated than extracts of normal organs, and we have a few direct experiments which show that a much smaller amount of tumor nitrogen is required to produce a fatal result than is required from extracts similarly made from autolyzed normal organs. These results agree with some of those found in the literature, but we are not able to say what the nature of these substances is, nor can we say that they are characteristic of neoplasms. Most experiments along this line have been so improperly controlled that they are of no value.

HEMOLYTIC SUBSTANCES.

There are a number of fragmentary observations on the hemolytic effects of tumor extracts, but many of these have been clinical observations under conditions not subject to experimental control, and in other cases the hemolytic effect of the extract has been tested against erythrocytes of an alien animal species, so that their value as a possible explanation of the anemia consequent upon malignant growth is of little value. The extracts should be tried upon freshly drawn and washed corpuscles of the same animal species, from which the growth came. Such a series of experiments Dr. Weil [14] has carried out in our laboratory during the last two years, using, as a source of his material, the transplantable lymphosarcoma of dogs. Extracts have been made of these tumors in all stages of their growth, and the hemolytic effect tested upon corpuscles of animals in all conditions of nutrition, and the results have been compared with extracts made from normal organs, in some instances blood free, and in others containing blood. We have had a further control by comparing results with those obtained from extracts of necrotic normal organs; for example, the renal artery has been ligated under aseptic conditions, and the kidney allowed to fall back into the peritoneal cavity and allowed to autolyze for from ten days to three weeks, and extracts then made in a similar manner as with the tumors. From such experiments we have found that extracts of normal organs containing blood are markedly hemolytic. Extracts of blood-free organs are very slightly hemolytic, but this extract may be activated by the addition of a very small amount of hemolyzed red blood cells. Extracts of fresh, vigorously growing tumors are more hemolytic than those from most normal organs, but it is with the necrotic organs and tumors that the most active hemolytic extracts were obtained, and with these the activity is, in some instances, a hundred fold greater than with extracts from non-necrotic organs and tumors. Apparently, the necrosis and subsequent autolysis of the tissue has set free substances which are readily soluble in a normal saline solution. The blood serum inhibits the hemolytic effect of extracts from normal organs or non-necrotic tumors, but has no effect upon the powerful hemolysins in necrotic tumors. One need scarcely add that it is in cases with large necrotic tumors that we see the most profound anemia and cachexia.

During the last few weeks, we have obtained some additional evidence that the hemolytic substance in the tumor is really a factor of importance in causing this anemia. We have found that the serum of animals having comparatively large, rapidly growing tumors is hemolytic, and this hemolytic effect is most marked upon the corpuscles of normal healthy animals, and much less marked upon corpuscles of the anemic, cachectic animals in which the tumors are growing. It seems that the corpuscles in the latter case have acquired some degree of immunity to the hemolytic agent present in the serum, while the corpuscles of the normal animal have not been exposed to such an agent and are consequently much less resistant. A practical result from these studies was seen in one case where an anemic, cachectic dog with fairly large rapidly growing tumors was transfused with the blood from a strong, healthy, normal animal. Following the transfusion, there were evidences of hemolysis, and test tube experiments showed that the serum of the tumor animal taken at the time of the transfusion was markedly hemolytic for the corpuscles of eight other normal animals.

We have no experimental evidence that other cells in the body beside those of the blood are attacked by tumor extracts in the same fashion, but I am inclined to believe that the blood cells are no exception, and that other tissues suffer from this lytic action.

ENZYMES IN TUMORS.

With reference to enzymes there has been some comparative study regarding the relation of tumors to normal organs, as has been noticed above, with regard to hemolytic effect, character of proteids, toxins and inorganic salts. The first of these observations had regard to the autolytic activities of tumors. Petry,[15] Wolff and Neuberg have noted the rapidity with which tumors undergo self-digestion, and I think no one who has made any chemical study of neoplasms has failed to notice how quickly they soften and what a large

percentage of non-coagulable nitrogen may be obtained from their extracts. A large number of the usual nitrogenous decomposition products have been isolated and identified, and many strange and unfamiliar substances have occasionally been met with in so small quantities as not to permit of further study. There are some apparently authentic experiments which show that the autolysis of tumors is hastened to a much greater extent by exposure to radium and x-ray [16] than is the case with healthy tissues.

Buxton and Schaeffer [17] in our laboratory have examined a large number of malignant tumors for a wide variety of enzymes. They have found nearly all the enzymes for which they searched. However, the difference from normal tissues as obtained by their methods, which were qualitative only, do not suffice to make any conclusion possible. These results merely show that tumors are rich in enzymes, but there has been found no specific enzyme which is present in one kind of tissue and lacking in the other, which will suffice in any way to explain the tumor process. Recently, we have heard a great deal about the heterolytic enzyme which is credited with being the toxic agent in the tumor cell. Buxton's study on the enzymes in tumors showed that many tumors have proteolytic enzymes and that these enzymes will diffuse out to a sufficient extent to digest some of the surrounding proteid. However, in no case did he obtain a proteolytic action on egg albumen. The presence of the proteolytic ferment was determined by the action on milk and gelatin. Fibrin and serum were never affected. Wolff and Blumenthal [18] have, however, more recently claimed to find .marked digestive effect upon liver proteid, but this conclusion is based upon a single experiment and under conditions *in vitro* which are foreign to physiological action. There are some statements to be found in literature from other observers in regard to heterolytic enzymes, but these are of so fragmentary and irresponsible a character, and so lacking in details of the experimental method used that one cannot decide either for or against their validity. It seems to me that such an active autolytic process as we find in a tumor may very well sweep into its field of action a foreign proteid that may happen to be present, but this autolytic activity differs in degree only and not in kind from that possessed by every normal organ. A demonstration that a malignant tumor contains an enzyme capable of absorption in the body fluids, and capable of marked digestive effect upon other tissues under physiological conditions, would be a contribution of definite value, and is something we now lack. It may be that the toxic properties of tumor extracts are in large part a function of the hemolytic and heterolytic activity.

The chemist has thus far laid only a small stone in the structure of our tumor knowledge. We know more than we did five years ago, but apparently are not much nearer a solution of the chemical phases of the problem. I believe, however, that the biochemical activities of a tumor cell are quite as important matters for consideration as the histological appearance, and we shall not really appreciate what a tumor is until those activities have been explained.

THE "OPTOMETRIST."
A WARNING WORD.

BY JOHN C. BOSSIDY, M.A., M.D.,
Ophthalmic Surgeon, Boston City Hospital.

EVERY physician practicing medicine in Massachusetts has received, or will receive within a few days, a circular from the Massachusetts Optical Society entitled: "A Few Facts Pertinent to the Optometry Bill," and also a copy of the bill which it proposes to introduce in the coming legislature, together with explanatory remarks by the chairman of the society's legislative committee.

Since the physician in general may never have heard the word "Optometry" or "Optometrist," it is well to explain this in detail. The optometrist, so called, is an optician. The word is but three years old, officially, and its history is as follows:

It took much time and thought to settle on this word, inasmuch as its sponsors discussed "Optist," "Opticist," "Ocular Refractionist," "Neurologist," "Neurometrist," and "Optometrist" as their would-be title.

The opticians, after forming state societies, organized a National Association of Opticians a few years ago, such association revolving in great part around a wholesale optical house in Boston. In 1903 and 1904, Mr. Eberhart, of Dayton, Ohio, was president of such National Association. In the *Optical Journal* under date of November, 1903, page 658, we find this advertisement:

> "This is a cut of the word 'Optometrist' furnished us by Mr. Eberhart, President of the American Association of Opticians, and supplied by us to any optician, postage prepaid, to any address, on receipt of thirty-five cents. We have already sold quite a large number, which is a pretty good indication that this word, coined by Mr. Eberhart, is a popular one and likely to be adopted by the American Association at its Milwaukee Convention in 1904."

Later, in the same journal, we find an advertisement reducing the price of the cut "Optometrist" to the significant sum of thirty cents. This, an official advertisement, proves absolutely that any optician could, or can, become an Optometrist by buying a sign and paying thirty cents therefor.

In the *Optical Journal* of Aug. 4, 1904, the same Mr. Eberhart, as president of the National

Association of Opticians, in his address of welcome at their annual meeting in Milwaukee, defined "Optometry" as "The Science which Treats of the Physiology of the Functions of Vision and the Physical Effects thereon by Lenses." Such word was, I understand, finally adopted as the title of the optician.

In the same address, the gentleman used the identical arguments from firstly to sixthly, which are found at the head of the circular being mailed this week to our Massachusetts physicians.

These arguments, then, are not original with our Massachusetts opticians, nor are they original with Mr. Eberhart, as he gives credit to a Mr. Prentice, of New York, for them, and they therefore contain the composite or combined wisdom and literary ability of many opticians.

Now, then, since any optician can call himself an "Optometrist," and (if their bill should go into effect) could be legally recognized as such, it is well for the physician in general to understand that the bill makes no difference with the standing of the optician except this:

The traveling vender of glasses, who now sells them in the country districts and disappears, would then have a certificate containing his name and number, and would be obliged, on the consummation of a sale, to give a receipt of sale to the customer containing his name, postoffice address and certificate number. He would not know any more then than he did when unknown, nor would any of the men registered and continuing in one place of business be any wiser than before the issuance of their certificate.

Every one who for two years preceding the passage of this bill had been in the optical business in the slightest refractive way could be registered without examination; even the boys who grind lenses at a wholesale establishment and who are members of the Massachusetts Optical Association could be registered and become a thirty-cent professional man, provided after working hours they (as they frequently do) fitted glasses at their home or the homes of any customers whom they could secure. I am, when I say this, not forgetful of the reading of section 5, of their bill:

> "Upon submitting to said board satisfactory proof as to his character, competency and qualifications, to receive from said board a certificate of registration."

That reads well; means little. Try to legislate a man out of business and you must provide for a law annex and a court of appeals.

Within a radius of a hundred yards in Boston, we find one man whose picture and advertisement proclaim him the greatest eye-sight specialist of the present day; while across the street is a man teaching what he calls the greatest system of eye and nerve measurements in existence, and formerly furnishing his students with a diploma and degree of Doctor of Optometry for $10.00. Not a stone's throw away is a third, whose picture and advertisements, scattered broadcast through the mail, proclaim him the one man in America who can absolutely correctly measure the eyes. Across the street, we find another optician working under the system of the celebrated Dr. "Blank," whose diploma, granted under the laws of Kansas, would make you an Opt.D. And finally, we note within this same circle the man whose name appears appended to the circular so recently sent to all medical practitioners in Massachusetts, and who modestly signs himself, "Chairman of the Legislative Committee." He neglects to mention his greatest title, or highest honor, for he is now the president of the National Association of Opticians; nevertheless, he is working under no general system, but under another celebrated "Blank" system.

He has written recently a paper entitled: "Massachusetts needs an Optometry Law," and your writer will later pay especial attention to this same book. In this connection, I cannot forego quoting from the remarks of this young gentleman, Mr. Palmer, at the tenth annual meeting of the New England Association of Opticians, held at Boston, May 17, 1904:

> "The best men," he said, "make a charge for their skill, and this is as it should be." He stated emphatically: "We can refract better than the oculist, and if we consider the total cost of an oculist's services and the charge of the dispensing optician for putting up the prescription, we can do work *not only better* than they, but **cheaper.**" If this is true, why not come out in the open?

Another remark of this same gentleman in his monograph, is worthy of quotation:

> "The oculist's or (more strictly) the ophthalmic surgeon's sphere of work is the treatment of diseased eyes and the performance of operations when necessary."

The inference is that the physician is incompetent, and should not be allowed to refractively examine the eyes of patients. In fact, the opticians have gone on in their claims until they not only pretend and advertise to know more than the oculist, but to define and limit the oculist's sphere of work.

They once possessed in Massachusetts an Optical College, which was incorporated under the laws of the state in 1899, with no opposition from the medical fraternity. Two years later, they petitioned the legislature for permission to grant degrees, such degrees to read "Bachelor of Optics" and "Bachelor of Physiological Optics." Such legislation was refused, and the College died soon afterwards.

Coupled with it, before the Committee on Education, was a bill to allow a Springfield school to grant the degree of "Doctor of Pedagogy." Such legislation was refused, and within a year the school moved to the neighboring state of Connecticut.

It would therefore seem that the life of these colleges depended on state aid in the sense that when hey could not get authority to grant degrees, they had no object for existence. The reasons for the passage of their bill are adroitly worded and put to catch the unwary. They can be easily answered, and such answer will be forthcoming at the proper time.

The gist of their argument to medical practi-

tioners is this: "Many people in the country, some in the city, are fleeced by the traveling or incompetent vendor of glasses. Would it not be better, where no oculist is at hand, to have an optometrist, of whose ability you would be certain, do the examination?"

Naturally the physician may say, "yes," and perhaps will sign their petition for legislation to recognize so-called Optometry.

This happened in New York to the extent that more than seven hundred physicians were said to be actively interested in the passage of a bill, establishing the optical trade as a medical specialty, and granting state registration to these gentlemen for the practice of their "profession."

They gave us a similar experience in 1901, in this state, when they petitioned for degrees. A copy of their petition showed the names of many doctors in regular standing in the Massachusetts and Homeopathic Societies, and one of them a vice-president of the Massachusetts Medical Society. They had been reached and their signatures had been secured by some specious argument, as for example: "We desire to become better educated; we seek to elevate the standing of our business or profession. To that end, we wish a college where mathematics, optics, physics and allied subjects, pertaining to the science of light and lenses, would be taught."

The physician naturally applauded such honest endeavor, and as a result loaned his name, but later sorrowfully avowed that he had mistakenly given his approval to an unworthy cause. It is to be hoped that such will not be the result of the present circular. Physicians should withhold their signature and approval until they have seen, read or weighed both sides of the matter.

In this connection, please again read your circular signed by Mr. Palmer; then read the following, sent to his fellow opticians:

BOSTON, Dec. 16, 1907.

Dear Sir: As you know, the Massachusetts Optical Society will present the enclosed optometry bill to the incoming legislature. The importance of this action is very apparent to any one who has kept in touch with the drift of the *controversy between the opticians or optometrists and the oculists.*

We are sorry to find you are not a member of the society, and most earnestly urge you to join. We do not believe you will want to have this bill passed without having helped to bring it about. *Now is the time to get on to the band wagon. Don't delay.* Fill out and return the enclosed application blank *at once.*

Your legislative committee is not only giving freely of their money but also taking many hours from their business to devote to this work. We believe every optician and optometrist in the Commonwealth should give something, even though it is a small amount, to help defray the campaign expenses. Our printing bills, stenographers' bills, stamp bills, etc., are very large and we must *have your financial help.* Don't put this letter aside until you have sent as much as you can spare to the treasurer. . . .

We have sent a letter and considerable printing matter to the editor of every newspaper in Massachusetts. Let us urge *you* to make a personal call upon *your editors at once,* asking them to give our letter and enclosures most careful consideration and impress upon them the importance of this legislation. We have also sent a letter and the bill to every physician in Massachusetts. *Go at once* to all the physicians in your section, asking them to sign the postal we enclosed in their letters. See all the members of the legislature in your section *at once.* Give them a copy of the bill and all other information as outlined in the booklet you received some weeks ago.

Send the committee the names of all legislators with whom you have any influence. You can have all the printed matter you want by sending word to the committee. Please enclose stamps, for our stamp expense is very large. If *you* do as we have requested, the success of the bill is assured. *Do your share at once.* . . .

Emphasize these points. *Do it now. Get busy along this line. Don't forget your contribution.*

Yours very truly,

BRIGGS S. PALMER,
Chairman Legislative Committee.

He starts with a misstatement, — there is no controversy between oculist and optician. The bill aims at the heart of every medical man in Massachusetts, in proof of which I can state, and do say so now, that the Boston Homeopathic and Massachusetts medical societies (through their respective legislative committees) have unanimously voted to oppose, in every honorable way, the passage of this bill. Gentlemen, think twice before you act; do not permit your editors and legislators to be misled; ask them to suspend judgment.

In conclusion, let me say that the passage of this law means this, — no more, no less:

The dignifying of their trade; the cheapening of our profession and the letting down of the bars which guard the practitioner and the public.

STRAIN AS A CAUSATIVE FACTOR IN INFECTIOUS ARTHRITIS.

BY JOHN D. ADAMS, M.D., BOSTON.

INFECTIOUS arthritis, so-called for want of a better term, presents in its many manifestations one of the most perplexing and important problems in orthopedic surgery.

We find this disease in one form or another in a large percentage of our clinic cases. In this working class of people it usually means that the patient is more or less incapacitated for work, and our treatment becomes a vital issue to a bread winner.

Experience has shown the hands to be a common seat of the trouble, and in a large majority of cases the primary manifestation, and the object of this paper is to report the observations on six cases all occurring in patients with the same occupation, with an attempt to discover a common factor as to cause. The histories of three of these cases are sufficient to illustrate all the points in question. They do not present anything very unusual except as to certain common factors.

CASE I. Dressmaker, fifty years old. Has been pursuing present work for ten years. Three years ago began to have pain in the terminal phalangeal joints of right hand, especially in middle finger, on which she wears thimble. Pain has been intermittent in character but has grown progressively worse, inconveniencing her materially in her work. In the last year the pain and swelling have spread to the metacarpo-phalangeal joints, the trouble having appeared in the other hand also. She has gradually lost motion

in many of the joints and has become totally incapacitated for work, owing to excruciating pain. The ordinary routine treatment has been without effect.

Examination shows very much deformed hands, right worse than left. All of the middle phalangeal

X-ray of right hand of Case 1, following operation (Keene).

joints distinctly dislocated and many of the terminal phalangeal joints turned at right angles; joints practically immovable from the point of usefulness. No involvement of wrist or any other joint.

CASE II. Dressmaker, forty-five years old. Has been pursuing present work for five years. One year ago began to have pain in the phalangeal joints of right hand, especially on thimble finger. This trouble has spread rather rapidly to all the joints of the right hand. Six months ago began to have trouble in left hand. Except for certain muscular pains has had no other symptoms. Joints of hand have become progressively worse, suffering pain and having exquisite tenderness when joints are touched or moved. Patient has become practically incapacitated for work.

Examination shows a uniform, fusiform swelling of all phalangeal joints. Subacute inflammation, very tender to touch and capable of very little motion. No fluid present but distinct thickening around joints.

CASE III. Dressmaker, forty years old. Has been pursuing present occupation for ten years. For past three years has had intermittent pain and more or less trouble in hands. Does not remember in which hand the trouble began, but it has been entirely confined to the phalangeal joints. Has been free from trouble for periods of six months at a time and has not noticed any great amount of swelling. For past two months has had acute pains in phalangeal joints of both hands, markedly increased on attempting to use them.

Examination shows slight swelling of phalangeal joints of both hands. Motion possible but rather painful. No fluid. Some thickening.

X-ray of these cases shows a hypertrophic condition in the affected joints, as evidenced by thickened periosteum. No destruction of joint or other pathological condition.

The other three cases present practically the same history in different stages of severity, but it occurred to the writer that these three cases illustrated the three different stages and character of onset sufficiently to appreciate the points of interest.

Analysis of these cases will show many common factors, namely, vocation, seat of disease, sequence of joints attacked, symptoms and relief to treatment.

In considering vocation as a factor one must not only analyze the character of the work but also the conditions under which it is done. Careful investigation showed that all these dressmakers worked in dry, well ventilated rooms, not exposed to drafts and in an even temperature. Their work, ten hours a day, was chiefly on very heavy goods, mostly men's clothes. Case I, which showed the most advanced stage, had been handling very heavy cloth, chiefly overcoating and riding breeches.

It will also be noted that the symptoms were first noted in the thimble finger, and the histories show a progressive infection of the joints in right hand before any symptoms occurred in the left. The onset was more or less insidious and symptoms not especially acute, but in all the cases, intensified greatly with use.

The pain, intermittent in character, was more in the nature of a soreness rather than the throbbing pain of an infection. The symptoms were not affected to any extent by sudden changes of temperature. In all the cases there was absolutely no indication of any trouble in any other joint in the body. In other words, the trouble was absolutely confined to the hands. The problem confronting one in these cases is, to say the least, a serious one, as we have a patient otherwise perfectly well but incapacitated for making her daily bread. Such a condition of affairs brings about the most pronounced type of mental depression.

The following line of treatment was pursued in all the cases: Urinary examination showed a marked hyperacidity in all the cases.

General treatment. — Diet: Omit all meats. Forced liquids.

Sodium benzoate, gr. v, t. i. d., to neutralize acidity.

Local treatment. — Baking daily.

This was done entirely by electricity. In the more acute cases a very intense heat was used, namely, a 100 candle-power light, applied for a period of twenty minutes, close enough to be tolerated by patient over bare skin.

In other cases, a small wooden box, one foot square, was made with two small apertures, large enough to insert hands, in one end. The box was lined with asbestos to prevent radiation, and fitted up with six 16 candle-power incandescent

lights. A temperature of 300° was maintained here for a period of twenty minutes.

The results were most gratifying. The counter-irritation of the heat produced the usual hyperemia to a marked degree, and all the cases showed a gradual diminution of pain, with a return on failure in systematic baking. The cases pursuing the treatment conscientiously for two months had entire relief from pain, with ability to return to work.

Case I was operated upon following her treatment, owing to the fact that she was unable to hold her needle on account of her extreme deformity caused by complete dislocation of all her metacarpo-phalangeal joints.

Under ether the adhesions were entirely broken up and dislocations reduced. The head of the third metatarsal bone on the right hand was removed; on the left hand it was partially removed leaving enough joint surface to make some motion possible. The hands were put up in plaster for ten days when manipulation was begun. One year after operation the deformity has not recurred to any extent, and she has some considerable motion in joints. The patient has had absolutely no pain for six months — in the absence of any baking — and is able to pursue her work.

Now, whatever the cause in this class of cases, whether of chemical or bacteriological origin, the writer feels justified in considering strain as a causative factor. It will be noted that in four of the cases the symptoms started in the thimble finger, that all of the cases worked with very heavy goods and that the trouble in all of the cases was confined to the hands.

There is nothing new offered here in the line of treatment, but the writer believes that with consistent baking and diet the pain in these cases may be controlled, and that in cases of extreme deformity operation is to be favorably considered.

Clinical Department.

PSEUDO-TUBERCULOSIS OF THE PERITONEUM. REPORT OF A CASE.

BY FARRAR COBB, M.D., BOSTON,
Assistant Visiting Surgeon to the Massachusetts General Hospital.

If, during an abdominal operation, miliary tubercles are found studding the peritoneum to a greater or lesser extent, it does not follow that the disease is true tuberculosis of the peritoneum. While the majority of cases presenting such an appearance will prove to be tuberculosis, in a certain small percentage, especially where there is little or no fluid, the case will turn out to be one of pseudo-tuberculosis caused by foreign bodies.

I report the following case of my own, not only because of its pathological interest, but also to emphasize the fact that in the absence of ascites, intestinal adhesions and enlarged mesenteric glands, the presence of tubercles on the peritoneum should not lead to a positive diagnosis of a serious disease, or to a gloomy prognosis, without thorough exploration of the abdomen and a careful microscopic study of the nodules.

B. G., married, twenty-eight years old, entered the West Surgical Service of the Massachusetts General Hospital, Dec. 20, 1900. She was placed in my care by Dr. Beach, the senior surgeon of the service. She had been recommended from the Out-Patient Department, because of a lacerated cervix and perineum.

Family history, unimportant.

Previous history: She had been well until the birth of her child, eighteen months before. Catamenia had been regular and not painful. She had always been constipated. No history of gastric or intestinal indigestion could be obtained, or anything suggestive of a previous gastric or duodenal ulcer, of typhoid fever or appendicitis. Since the birth of her child she had had severe dysmenorrhea with constant pain in the lumbar region shooting down into the right sciatic nerve. She had not been able to walk the last few weeks because of this pain and because of a bearing-down feeling. She had had cutting pain in the rectum and across the lower part of the abdomen, especially when at stool. There had been no headache, no vomiting and no bladder symptoms.

Physical examination: A well developed and nourished woman. Heart and lungs normal. Vaginal examination showed a torn perineum with marked cystocele and rectocele with a decided sagging of the pelvic floor and prolapse of the uterus, which was of normal size. There was a bilateral tear of the cervix. There was some tenderness on pressure in both broad ligaments with a slight induration in the right. The right ovary was enlarged and tender and entirely prolapsed behind the uterus. Rectal examination discovered a few moderate sized internal hemorrhoids. Both the temperature and pulse were normal during her stay in the ward previous to operation.

She was operated upon by me on the 26th of December, 1900. The usual plastic operations for the cure of the cystocele and rectocele and repair of the cervix and perineum were done, after which, with the patient in the Trendelenberg position, the abdomen was opened in the median line by a two and one-half inch incision. The abdominal operation was undertaken for the purpose of suspending the prolapsed uterus and correcting the displacement of the ovary. After making the incision it was seen that the surface of the peritoneum everywhere, and especially in the pelvic region, most marked on the surface of the uterus, tubes and ovaries, was studded with small miliary tubercles presenting a typical picture of tubercular peritonitis. There was no free fluid in the abdominal cavity, no intestinal adhesions and no enlarged or palpable mesenteric glands. The appendix was small and normal. The stomach and duodenum were not examined, unfortunately, for signs of old perforating ulcer. Because of the possibility of what was thought to be a tubercular peritonitis arising from disease of the Fallopian tubes, both tubes and ovaries were tied off and removed. The uterus was suspended and the abdominal wall was closed in layers with chromicized catgut. Three pints of normal salt solution were left in the abdominal cavity. The foot of the bed was elevated for reversed postural drainage.

There was no reaction from the operation either in the pulse or temperature. Convalescence was uneventful. The peritoneal and abdominal wounds

healed by first intention and the patient left the hospital, Jan. 20, in good condition.

The pathological examination of the tubes and ovaries removed discovered the fact that this was not a case of tuberculosis, but that the tubercles were due to the irritation of true foreign bodies. A determined investigation was made to discover some history of antecedent acute abdominal disease, which might be interpreted as a visceral perforation, but without success.

The pathological report on the case was made by Dr. Wright, the director of the pathological laboratory, and was as follows:

"In chronic inflammatory tissue on the ovary and Fallopian tube are some peculiar circular nodules, about the size of a miliary tubercle. These are composed of epithelioid cells and in some instances also of giant cells, the margins of which — the tubercles — are encapsulated with dense connective tissue. In the interior of some of these nodules are foreign bodies suggestive of the remains of vegetable material. These circular nodules are not true tubercles of tuberculosis, but are typical foreign body tubercles."

Numerous sections of the specimens were made by myself and studied with various staining media and reagents with a view to determining the nature of the foreign bodies. These in every case showed bright opalescent green with a high refractive index under all

FIG. I. Nodule on surface of the right ovary, under low power. Note giant cell close to foreign body, also ring of connective tissue.

staining methods and presented a marked striated appearance, suggestive of the teeth of a comb or not unlike the ribs of certain vegetable fiber. The figures annexed to this article show fairly well the histologic

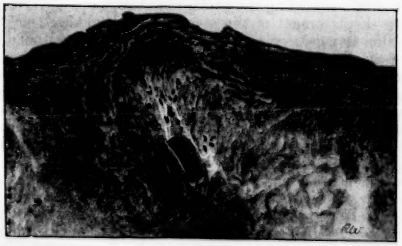

FIG. II. Foreign body and immediate neighborhood under high power. Note the striated appearance.

nature of the tubercles, the dense ring of connective tissue, the numerous epithelioid cells and occasional giant cell, with the green, highly refractive body in the centre.

The woman remained well with no sign of abdominal disease for three years after her operation, when she was last seen by me. Further attempts to follow up the case have been unsuccessful.

There are several varieties of pseudo-tuberculosis which are of interest chiefly to the physician. If these forms involve the peritoneum the tubercles found are always in association with disease of other organs, especially of the lungs. The chief causes of these complex forms of pseudo-tuberculosis may be summed up as bacilli different from tubercle bacilli and various mold fungi. Foreign body tuberculosis of the peritoneum is of special interest to the surgeon. It can exist independent of organic disease elsewhere. It may be caused by the irritation of true foreign bodies reaching the peritoneum through visceral perforation or by particles from ruptured intra-abdominal cysts, hydatid or dermoid. A number of cases have been reported in which pseudo-tuberculosis of the peritoneum has been caused by the hooklets from ruptured hydatid cysts or by small pieces of cyst membrane. Dévé, in a clear description of the appearance of the tubercles in this form, says they resemble true miliary tubercles to the closest microscopic detail. He refers to a case reported by Lehne who noted a similar pseudo-tuberculosis of the meninges caused by the rupture of a hydatid cyst of the spinal column.

Meyer has reported a case in which minute cholesterin crystals from a ruptured dermoid ovarian cyst were the irritating particles which caused the peritoneal tubercles. An unusual case has been reported by Helbing in which the eggs of the tenia worm were the foreign bodies found in the center of the miliary tubercles. These must have gained access to the peritoneal cavity through some defect in the wall of the intestine; Helbing suggests a perforated appendix.

A small number of cases have been reported in which the tubercles were caused by true foreign bodies. In the majority of the cases these were presumably fragments of vegetable food, as in my own case. The point of entrance of these particles of food must be through some defect in the gastro-intestinal tract, perforation of gastric or intestinal ulcers, diseased appendices or diverticula. Cases have been reported in which this form of pseudo-peritoneal tuberculosis followed a perforation of the stomach, notably the cases of gastric ulceration with perforation reported by Hanau and Cooper in which the miliary tubercles were found post-mortem, and after study were discovered to be due to fragments of vegetable food. The tubercles in both these cases were apparently similar to the case here reported, but in my case no history suggestive of gastric or intestinal perforation or even of previous digestive disturbances or of acute abdominal attacks could be obtained.

Practically it should be recognized that foreign bodies escaping from the stomach, intestines or from cysts may cause an apparent miliary tu-

bercular peritonitis, and the finding of tubercles without the accompanying signs of tuberculosis, enlarged mesenteric glands, ascitic fluid and intestinal adhesions, should lead to a thorough search of the abdomen, to the excision of one or more of the tubercles for microscopic examination, and to careful investigation as to previous digestive disturbances.

Reports of Societies.

INTERNATIONAL DERMATOLOGICAL CONGRESS.

SIXTH INTERNATIONAL DERMATOLOGICAL CONGRESS, HELD AT THE ACADEMY OF MEDICINE, NEW YORK, SEPT. 9 TO 14, 1907.

THIRD DAY, WEDNESDAY, SEPTEMBER 11.

(Continued from No. 25, p. 831.)

THE first two hours of the session were devoted to the exhibition of patients and formal discussion on the same.

DR. VEIEL, of Cannstatt, Württemberg, and DR. H. HALLOPEAU, of Paris, France, in the Chair.

BLASTOMYCOSIS OF THE SKIN,

by DR. M. OPPENHEIM, of Vienna, Austria. The author stated that the first case in Europe conforming with the American cases of this disease (pseudolupus) was observed in Neumann's clinic in Vienna, by the writer, in 1904. Later he had occasion to observe three others. The clinical picture in the earliest stage was a light, red-stained, swollen lesion, with characteristic pustules. From the latter, superficial ulcers with irregular margins arose, which produced superficial scarring. Histologically, there were intra- and subcorneal and intra-epithelial abscesses; the rete pegs were increased in size and the stratum papillare was infiltrated by round cells. In the abscesses and infiltration were found the blastomycetes, singly and grouped, but never abundantly. As the lesions grew older, the picture was similar to lupus verrucosis, with elevations surrounding cicatrized areas, thickening of the nose and lip, excoriations and deep ulcerations with irregular margins and uneven base covered by thick crusts, sometimes destroying the nostrils and perforating the septum of the nose. From the base of some of the ulcers papillary excrescences soon overgrew the margins and showed points of cornification. Microscopically, there was an overgrowth of epidermis and an infiltration of the corium with round, plasma and giant cells, even to the subcutis. A few blastomycetes were present. The therapeutic effect of potassium iodide was evident in all four cases.

SYSTEMIC BLASTOMYCOSIS. A CRITICAL SURVEY AND SUMMARY OF NINETEEN CASES (FOUR OF THEM UNPUBLISHED).

DR. FRANK H. MONTGOMERY and DR. OLIVER S. ORMSBY, of Chicago, in this paper stated that about one hundred cases of blastomycosis involving the skin had been recognized, chiefly in Chicago and vicinity, but also in other parts of the United States, in Canada, in various parts of Europe, in Japan, India and South America. Of the 19 cases recorded in this paper, 12 were dead, 4 were dying, 2 had recovered, and 1 had disappeared from observation. All of the cases, with possibly one exception, presented multiple subcutaneous abscesses and nodes, usually indolent in type. With the appearance of the abscesses there had been in all cases a disturbance of the general health. The duration of the disease varied from a few months to two and a half years. Blastomycotic lesions had been demonstrated in practically all of the tissues and organs of the body. The characteristic changes consisted in the presence of nodules or abscesses in the soft tissues, and caries in the bones. The abscesses varied greatly in size. Necrotic areas in bones, containing the organism in abundance, surrounded by leucocytes, giant cells and other cells peculiar to the granulomata had been noted and fully described in one case. It was worthy of note that, notwithstanding the presence of extensive suppuration in most of the cases, in two only was amyloid degeneration recognized, and in only one were these changes at all extensive, occurring in the liver, kidneys, adrenals, spleen, the colon and in various lymph glands. The bacteriology of systemic blastomycosis was identical with that of the cutaneous form of the disease.

DR. JOSEPH ZEISLER, of Chicago, said he had seen many of the cases of blastomycosis reported by Drs. Hyde, Montgomery and Ormsby, and in order to illustrate the difficulties ofttimes connected with this subject, he referred to the case of a young woman, about twenty, who fell ill with a high fever, which pointed to a pulmonary infection of some kind. For many days a miliary tuberculosis was suspected, but no definite diagnosis was made. Finally, sufficient sputum was secured and submitted to Dr. Hektoen, who upon microscopic examination found the blastomycetes present.

DR. THOMAS C. GILCHRIST, of Baltimore, spoke of the similarity between the organism of blastomycosis and that of granuloma coccidioides.

DR. JAMES NEVINS HYDE, of Chicago, expressed the conviction that the organism which produced blastomycosis was more or less limited to a certain geographical distribution, and, for reasons he could not explain, that particular area was not very far distant from Chicago and Indiana. It was there that the organism seemed to flourish as it did nowhere else.

DR. HOWARD MORROW, of San Francisco, said he had had repeated opportunity to compare cultures of blastomycetes with those of the granuloma coccidioides, and he had found that they varied considerably.

DR. DOUGLASS W. MONTGOMERY, of San Francisco, said there was no doubt that there was a marked difference between the two fungi under discussion. Dr. Morrow had grown both of these organisms on the same media, and under the same conditions. One showed a halo; the other a clump of fungus. He had had no trouble in cultivating the Illinois micro-organism in California.

DR. OLIVER S. ORMSBY, of Chicago, said that blastomycosis was really a very serious disease, and one that did not belong entirely to the dermatologist. It was important, he thought, that this fact should be recognized. In the cases they had seen in Chicago, the skin had been involved in practically all but one instance.

THE THYROID AS A FACTOR IN URTICARIA CHRONICA.

DR. M. L. RAVITCH, of Louisville, Ky., claimed that chronic urticaria should be classified as a curable disease, and in connection with its treatment he made a plea for a more thorough study of thyro-therapy. He firmly believed that in many cases of chronic urticaria, thyroid extract was a specific. He claimed that disorders of the thyroid gland were the cause of many toxemic conditions, and that thyroid extract was an autotoxin; hence its usefulness in toxemic conditions,

urticaria chronica included. Chronic urticaria was more frequently among women than men, and the fact that functional thyroid disorders were also more common in women led the writer to believe that functional disorders of the thyroid were the cause of chronic urticaria. He regretted that thyro-therapy had been neglected in the treatment of skin diseases, and pointed to the fact that remedies useful in chronic urticaria were also useful in functional disorders of the thyroid gland. Outside of the eruption, the writer claimed, the symptoms of chronic urticaria were almost the same as in thryoid toxemia.

HYDROA PUERORUM (UNNA),

by DR. MARCUS HAASE, of Memphis, Tenn., and DR. ROSE HIRSCHLER, of Philadelphia.

After reviewing the recent literature on this subject, the authors reported in detail a case of hydroa puerorum seen with Dr. Unna, in his clinic at Hamburg, from which a biopsy was made. The histopathological findings in the case were also detailed, and an attempt was made to establish its proper place among the hydroas. In claiming for this disease a place in the nomenclature as a dermatological entity, the authors offered the following conclusions: (1) It was an acute erythemato-vesicular disease, preceded and accompanied by intense burning and itching. (2) The vesicles coalesced to form bullæ. (3) Involution of lesions without pitting or scarring. (4) The first attack occurred in the first year of life. (5) Recurrence of attacks independent of external influences. (6) Gradual lessening of attacks in extent, intensity and duration. (7) Spontaneous disappearance at puberty. (8) Unrestricted to any particular lesion. (9) Restricted to male sex. (10) Relatively normal health during attacks. (11) To these might be added the superficial character of the disease, the lesions being confined to the rete.

DERMATITIS COCCIDIOIDES; WITH REPORT OF A CASE,

by DR. A. RAVOGLI, of Cincinnati, Ohio. The case was reported under the nomenclature of dermatitis coccidioides because the parasite found in the lesions closely resembled a coccidium. The clinical features of the disease, although related to blastomycetic dermatitis, were somewhat different. The parasite taken directly from the ulcerated surfaces had a long thread of mycelium, but when cultivated on glycerin agar and on blood serum showed only round bodies, with scarcely any mycelium. Its growth was rapid and abundant and its development seemed to be due to endogenous proliferation. The result of the treatment was also different from that obtained in true blastomycosis.

DR. DOUGLASS W. MONTGOMERY, of San Francisco, said he could not make out the coccidioides in the sections shown by Dr. Ravogli.

At the conclusion of this session, Prof. Thomas De Anicis of Naples, Italy, was elected president of the next congress,which is to be held in Rome in 1910.

FOURTH DAY, THURSDAY, SEPTEMBER 12.

The first two hours of the session were devoted to the exhibition of patients and formal discussion on the same.

PROF. E. GAUCHER, of Paris, and DR. ANDREW R. ROBINSON, of New York, Vice-Presidents, in the Chair.

FURTHER EXPERIENCE WITH THE WHITE LIGHT AND BLUE LIGHT OF THE QUARTZ LAMP, WITH DEMONSTRATIONS,

by PROF. E. KROMAYER, of Berlin, Germany. (This paper was read by title.)

THE SPECIFIC ACTION OF RADIUM AS A UNIQUE FORCE IN THERAPEUTICS.

DR. ROBERT ABBE, of New York, said that radium ranked, not with caustics, cautery, antiseptics or medication, but with specifics. This did not mean a "specific" for cancer in the popular sense, but for erratic cell growths constituting some types of tumor tissue in the earlier stage of invasion or of moderate development. Details of the method of using it had not yet been fully worked out. The dosage, so to speak, or the time of exposure necessary for curative action, was as yet empirical. Some apparent cures of small epitheliomata or sarcomata had already endured more than three years. A photographic plate provided a good test to show the working force of an unknown specimen, in comparison with one of standard strength. It was not entirely a mysterious force; in part, at least, it was an electric discharge, essentially of negative elements. Hence, so far as it was possible to say, it suggested a theory of its action in that it might supply an element of electric force vital to normal and orderly growth, the loss of which might have caused a disorderly cell growth, which in the aggregate constituted tumor masses. It was supplementary to Roentgen rays and in some cases was efficient when the rays failed. The over-action of strong radium was destructive and vitiated the benefit of moderate use. The best results had followed one hour's exhibition of the working unit (10 mg. RBr) on small growths, and three to four hours on larger ones, with an interval of one month for study of the effect. Ischemia of the parts during treatment greatly enhanced its action. Pigmented moles, melanotic growths, and giant celled sarcoma, like epitheliomata of the eyelids, face and body, were particularly susceptible to its curative action as a specific agent. Its value in nevoid and angiomatous tumors was due to its irritant action, producing obliterating endarteritis and fibroid changes.

DR. JAY F. SCHAMBERG, of Philadelphia, said that unless it could be shown that radium was more efficient than the x-ray, there would be no advantage in preferring it to the latter agent. The advantages of radium lay in the simplicity of its application, and the fact that it could be used in inaccessible cavities, where the x-ray could not be applied.

DR. H. RADCLIFFE-CROCKER, of London, gave some experience with radium emanations obtained from a solution of radium.

DR. HERMAN LAWRENCE, of Melbourne, Australia, said that in cases of rodent ulcer of the eyelid he regarded radium as the best method of treatment. Combined with the x-ray, it was also of great value in keratosis senilis. In seborrheal eczema of the eyebrow, where one could not well use the x-ray, radium had proved very efficacious and without destroying the hair.

THE THERAPEUTIC EFFECT OF RADIUM IN DERMATOLOGY,

by DR. L. WICKHAM, of Paris, France. (Read by title.)

THE EFFECT OF ROENTGEN RAYS ON PAGET'S DISEASE OF THE BREAST,

by DR. TERZAGLII and PROF. R. CAMPANA, of Rome, Italy. The authors stated that some forms of psoric eczema of the breast and nipple frequently were neglected and at times seemed a chronic and malignant form, as of epithelial tumor, a form which had been named from the author first describing it as "Paget's disease." The authors then reported in detail the history of a case that threatened to assume the above form of disease, in which the affected tissues apparently resumed their normal condition under the appli-

cation of the Roentgen rays. The method was repeated in another case, with the same favorable results. These two experiments, Professor Campana said, did not seem to him to be without interest when we reflected on the extremely malignant course of Paget's disease.

PROGRESS IN RADIOTHERAPEUTICS,

by Dr. H. Strebel, of Munich, Germany. (Read by title.)

X-RAY BATHS AND DERMAMETROPATHISM.

Dr. Herman Lawrence, of Melbourne, Australia, described the x-ray bath as one in which the x-ray was applied to the skin of the entire body at one time, and he told in detail its method of application. The speaker said he had treated some 500 cases of skin disease by radiotherapy, and he believed that he secured better results by the method of giving several mild exposures as compared with the method of giving a heavy dose and then waiting to see the result on the patient's skin. He had used the bath successfully in mycosis fungoides, generalized eczema, psoriasis, obstinate urticaria and pruritus; also in children in very troublesome cases of lichen urticatus. Dermametropathism was a word he had coined; it was meant to express a system of measuring a disease of the skin, and was based upon the result produced upon the skin by pressure with a smooth instrument, such as a pen handle. The author contended that by this method of clinical observation, which he called "skin marking," certain markings indicated the chronicity of certain diseases, and in some cases in adults the near onset of a relapse; also, that it explained the exaggeration of symptoms in some cases.

A REPORT OF THE RESULTS IN A SERIES OF EPITHELIOMATA TREATED WITH X-RAYS MORE THAN THREE YEARS AGO.

Dr. William Allen Pusey, of Chicago, read this paper, of which the following is a summary: Of the 31 cases which were classed as not entirely successful, 28 had failed of relief under other forms of treatment; only 3 were primary cases. These 3 were included in the group of failures, and they were all carcinomata involving the orbit. They were inoperable and occurred in patients who had abandoned treatment before any result might have been expected. In this entire list of 29 unsuccessful cases, there were only 5 in which, in the author's opinion, there was any hope of cure by other methods of treatment. All of these 5 cases had previously been treated surgically, and all had been referred to him by surgeons. One case in the practically successful group was an epithelioma involving the external auditory canal. The other 4 cases were among the failures; in 3 of these there had been good grounds for expecting successful results from operation, but the patients would neither submit to operation nor complete their x-ray treatment. Among the entire list of 111 cases treated, there were only 3 failures, in which there was any reasonable hope of success. Twenty-eight of the 111 cases were either hopeless or most unpromising, so far as any other method of treatment was concerned; of the 83 remaining cases, 80 were successful. Counting 31 cases as failures, there were 80 successful cases in a list of 111 successive cases of epithelioma treated more than three years ago, a showing of 72.5% of successful results in 111 unselected cases.

REPORT OF 800 DERMATOLOGICAL CASES WITH X-RAY AND HIGH FREQUENCY CURRENTS AT THE MOUNT SINAI HOSPITAL. (DR. LUSTGARTEN'S CLINIC.)

By Dr. Samuel Stern, of New York. The author stated that the respective standing of radiotherapy in dermatology could only be established by continued experiments, and by collecting statistics of results accomplished. The method in which the x-ray did its work was probably by cell destruction, which led to the degeneration of the elastic and connective tissues. In epithelioma the results accomplished depended upon the proper choice of cases. The most favorable were those situated on the surface of the epidermis. The best results were achieved by a combination of x-ray and high frequency spark. In deep-seated carcinoma there was very little to be expected. It was more encouraging in the various forms of sarcoma. In acne vulgaris the results were very gratifying, while in acne rosacea there was little to be accomplished. In psoriasis the value of the x-ray was well established; also in different forms of eczema. Lichen chronicus, lichen planus and lichenoid eczema were conditions that were more stubborn, but they generally yielded to x-ray treatment. Lupus erythematosus did well with the high frequency spark treatment, but it often recurred. Lupus vulgaris affecting the mucous membranes was best treated with the x-ray, and other parts of the skin with the high frequency spark. Various types of verrucæ and nevi could be readily destroyed with the high frequency spark. In keloid, to expect permanent results, we must persist with the x-ray until a fair degree of dermatitis was produced. Folliculitis decalvans yielded well to x-ray treatment. Pruritus was benefited by both the x-ray and the high frequency current. Mycosis fungoides could be indefinitely controlled by the x-ray, but not cured. Unless the treatment was kept up, the lesions returned. In rhinoscleroma we could probably get a definite cure. In sycosis, favus and trichophytosis capitis the results accomplished with the x-ray were very satisfactory, but in the two latter conditions, other treatment was necessary. Hypertrichosis could be cured with the x-ray, but this required very careful technic. Hyperidrosis might be benefited, but only after a long series of treatments.

Dr. Neuberger, of Nuremberg, Germany, reported a case of Paget's disease of the penis, which was apparently cured under x-ray treatment. It subsequently recurred, however, and amputation finally became imperative.

Dr. M. B. Hartzell, of Philadelphia, said that while he was willing to admit that the proper treatment of epithelioma of the lower lip was excision, with removal of the contiguous glands, there were certain cases in which resort to the x-ray was entirely proper and sometimes necessary. In one case of typical epithelioma of the lower lip coming under the speaker's observation, the man refused radical treatment by the knife. After ten three-minute exposures with the x-ray the lesion disappeared, and the man had thus far remained well. He had avoided what he regarded as a very serious operation, and was now ninety-four years old.

Dr. Burnside Foster, of St. Paul, said he had seen deplorable results follow the x-ray treatment in cases of psoriasis, eczema, favus and ringworm, and they were largely due to the method in which the treatment was applied by inexperienced operators.

Dr. Francis J. Shepherd, of Montreal, said that in certain cases of epithelioma, notably in lesions about the eyelids, the x-ray was probably the best method of treatment, but when it came to lesions of the lower lip and of the muco-cutaneous surfaces, the speaker said he would strongly object to the use of the rays, especially where there was early involvement of the glands. Under those conditions, surgical treatment was strongly indicated.

Dr. William A. Pusey, of Chicago, said he was will-

ing to treat any epithelioma with the x-rays, in which a conservative surgeon did not consider it feasible or necessary to remove the contiguous glands. This at once eliminated all cases of epithelioma about the mucocutaneous junction where an operation was at all possible. It did not eliminate those in very old people, or those rare cases where an operation was not tolerated. Still, the x-ray should not be restricted to any particular field. If it was not as reliable in one case as in another, it was not worth while considering.

PROF. E. GAUCHER, of Paris, France, and DR. VEIEL, of Cannstatt, Württemberg, spoke in favor of conservatism in the use of the x-rays. The latter said he could recall many cases that were kept too long in the hands of the radiotherapists, and came too late to the surgeon.

The discussion was continued by DR. HERMAN LAWRENCE, of Melbourne, and was closed by DR. STERN.

AFTERNOON SESSION.

DR. J. NEVINS HYDE, of Chicago, PROF. ROBERT CAMPANA, of Rome, Italy, and DR. SAMUEL SHERWELL, of Brooklyn, Vice-Presidents, in the Chair.

THEME II. TROPICAL DISEASES OF THE SKIN.

THE RELATION OF THE NAVY TO THE STUDY OF TROPICAL DISEASES,

by DR. P. M. RIXEY, Surgeon-General, United States Navy, Washington, D. C. In this paper, which was read by Dr. G. E. H. Harmon, Medical Director United States Navy, Dr. Rixey made the statement that, taking a period of ten years, he had found that diseases of the skin had practically caused twice as great damage to the health of the navy as was caused by all other diseases of a quarantinable nature. When it was considered that he included such diseases as diphtheria, smallpox, scarlet fever, rötheln, etc., in this category, the basis for his statement could be appreciated. The actual proportion was as 1 to 1.8. Had he also included syphilitic affections of the skin, this disproportion would be greatly increased. Dr. Rixey said that when he was appointed surgeon-general of the navy in 1902, his first aim was to establish a school where the young officers of the medical corps of the Navy could be grounded in the essentials of medical research. Of the many tropical diseases due to animal parasites, and of the many which might hereafter be found to be of such etiology, it was his belief that for a proper appreciation of such conditions a sound working foundation in medical zoölogy was not only desirable, but essential. For honest and capable work in any branch of tropical medicine it was necessary that the worker be grounded not only in clinical observation, but he must possess a fair degree of proficiency in bacteriology, a good working knowledge of animal parasitology, and, besides, have enthusiasm for his work. The medical officers of the navy were, while in tropical waters, constantly required to study or treat such affections as ringworm, and the peculiarly virulent manifestations of syphilis. Also such diseases as yaws, leprosy, ground itch, elephantiasis, tropical ulcer and the like. The speaker also referred to gangosa, or rhino-pharyngitis mutilans, which was studied by Daniels in the Fiji Islands, and was unfortunately very prevalent in the island of Guam. Those who had studied it most carefully were positive that it was not syphilis and absolutely sure that it was not leprosy. Another puzzling affection was what was generally termed "climatic bubo." Here we had the picture of a prolonged continued fever following more or less the increase or decrease of the glandular swellings.

REPORT ON TROPICAL DISEASES OF THE SKIN,

by DR. WILLIAM DUBREUILH, of Bordeaux, France.

TROPICAL DISEASES OF THE SKIN.

DR. H. RADCLIFFE-CROCKER, of London, England, exhibited tables which showed that practically all exclusively tropical diseases of the skin were due to parasites of various kinds, and although there was still much room for further investigation, they also showed that much of our knowledge of their pathology had been worked out quite recently. Now that so many of those who were going to practice in the tropics were undergoing a course of training in modern pathological methods, we might well expect that in the near future still greater additions to our exact knowledge would be made. It was only exact knowledge which would enable us, not perhaps to treat the diseases themselves better than we did now, but, still better, to adopt the most efficient means for the prevention and spread of affections in which the disabling effects and mortality were so great. How much could be done in this direction the results of the discovery of the relation of the mosquito to filaria, malaria and yellow fever were known to all. The first of the tropical skin diseases discussed by Dr. Crocker was tropical ringworm, which he said was probably universal in all tropical countries. Among other tropical skin affections discussed by the writer was erythrasma, which was due to the microsporon minutissimum and developed in the form of patches in the groins in the axillæ; these lesions were dull red in cold weather, while in hot weather they became bright red and itching, and extended to neighboring parts. He also referred to the vitiliginous squamous dermatosis, which had been observed by Jeanselme on the coast of Annam and other parts of Indo-China; also to furunculosis orientalis and yaws, which he regarded as one of the most serious of tropical diseases on account of the severity of the lesions and of the enormous number of its victims in the countries in which it was endemic, which comprised, practically, the whole tropical zone. The main question was whether yaws and syphilis were identical or only analogous diseases. The clinical fact that the manifestations of yaws yielded to mercury and iodide of potassium, judiciously given, no doubt lent more color to the theory of identity, but it by no means proved it. He had met with one case of granuloma inguinale tropicum in a full-blooded negro, and with two cases of crawcraw from the west coast of Africa.

SOME AMERICAN PARASITES OF THE SKIN.

DR. CH. WARDELL STILES, of the United States Public Health and Marine-Hospital Service, Washington, D.C., spoke of the frequency of "ground itch" in the Southern states, in connection with uncinariasis, and gave a demonstration of preparations, showing the larval hook-worms passing through the skin. He also gave a presentation and description of specimens of a parasite new to the United States. This parasite was a branching, proliferating, bothriocephid, larval tapeworm, which occurred by hundreds in the subcutaneous connective tissue of man in Florida, and produced a swollen condition, with spots of acne-like appearance. The only similar case on record was published by Ijima (1905), of Tokyo, Japan. The American parasite was very similar to and possibly identical with the Japanese form (Sparganum proliferum). He also gave a demonstration of original specimens of Agamofilaria georgiana, a thread-worm recently described as a parasite in the skin of man in Georgia. Also, a demonstration of various stages in the life history of some of the North American ticks (particularly dermacentor), which attacked man.

THE CLINICAL GROUPINGS OF TROPICAL ULCERS OF THE PHILIPPINES, WITH SOME NEGATIVE NOTES AS TO ETIOLOGY AND TREATMENT,

by Dr. E. R. Stitt, of the United States Navy. The author stated that after observing in the natives many chronic ulcerations, which clinically did not differ from ulcerations which might be expected from badly infected and neglected wounds, or from the infective granulomata, and that from a standpoint of history there was the single common note of long duration, the conclusion was arrived at that tropical ulcer, as described by the authorities, did not exist in the Philippines. Subsequently, the same thing was observed in Guam in studying an ulcerating disease known as gangosa. Among the natives affected with leprosy and gangosa there were a certain number, called by the Spaniards the Llagosos, in whom there were frightful lesions of the lower extremity, possibly tuberculous, possibly tropical ulcer. Later on, among sailors at the Naval Hospital, Canacao, two distinct types of chronic ulcer were observed, the first conforming to Fayrer's description of Delhi boil; the second resembling Jeanselme's tropical phagedena. Smears from ulcers of the first type showed scarcely any polymorphonuclears, only cells of lymphocyte characteristics. There was nothing indicative of protozoa (Giemsa's stain). Smears from ulcerations of the second type showed the presence in abundance of a single organism, morphologically a corynebacterium. Polymorphonuclears were present in great profusion; no cocci. Among the methods of treatment reported negatively were mentioned the following: (*a*) artificial gastric juice; (*b*) excision of lesion; (*c*) cauterization with pure carbolic acid; (*d*) Bier's passive congestion; (*e*) massive doses of potassium iodide.

GANGOSA; WITH ADDITIONAL NOTES,

by Dr. O. J. Mink and Dr. N. T. McLean, passed assistant surgeons, United States Navy, Washington, D. C. Since the publication of their original paper on this subject in 1906, additional literature, not available at Guam, had been studied, and a few further facts regarding certain phases of the disease had been obtained. The disease had existed in Guam for at least one hundred and fifty years. Although only 125 cases had been examined at Guam, there were probably between 200 and 250 on the island, the population of which was about 11,000. The youngest ages at invasion were three and nine years; the oldest were fifty-four and fifty-nine years. In a series of 80 cases, 49 were in females and 31 in males. The natives of the various parts of the island were intimately associated by religious, marital and commercial relations, but there was no evidence to show that heredity played any part in the transmission of the disease. The native theory, and that held by the Spaniards, gave food a prominent place in the causation of the disease. They believed that such foods as decomposed or very salty fish, especially if eaten raw, uncooked taro and native pepper were the direct causes of the disease. This theory seemed improbable. The disease had been considered a late manifestation of syphilis, but the authors stated that during eighteen months spent in Guam they did not see syphilis of any type among the native population, and they did not believe that it existed there. Their observations led them to believe that if there was a specific infecting agency, the nature of it was yet undetermined. The majority of the cases occurred in pure blood natives. As the disease was not fatal, autopsy was only possible when death occurred from intercurrent disease. To those who had seen a case of gangosa, the diagnosis offered no difficulty. In a number of cases observed, the initial symptoms led to a diagnosis of tonsilitis, pharyngitis and laryngitis of a mild degree. All showed a slight rise of temperature, and complained of soreness in the posterior nares and pharynx, with stiffness in the muscles of deglutition. The throat symptoms became localized, and on the third day a patch of yellowish gray membrane was observed on the soft palate in the first case, the uvula in the second, and on the right pillar in the third case. The membrane was elevated, thick and tenacious. On removal, the denuded surface bled freely. Within twenty-four hours of the appearance of the membrane, the typical ulceration was established. On the area covered by the membrane, a number of small depressions appeared. The ulcer which was formed had a punched-out appearance, with undermined edges, and a deep, uneven floor, covered with a yellowish-white and very offensive discharge. The depth of the ulcer rapidly increased, until, in the cases of the uvula and soft palate, the tissues were perforated by the seventh day. These cases were still under observation. Fulminating gangosa was differentiated from diphtheria by the absence of Klebs-Lœffler bacilli, and by the typical mutilation in those cases which survived. Excepting in the fulminating type, the disease, *per se*, was never fatal. The mutilations and complications were permanent, and caused corresponding disability. The treatment was essentially local, and should aim to destroy the infected area.

Dr. W. F. Arnold, lieutenant-commander and surgeon (retired), United States Navy, said that he had been able to differentiate clinically the condition known as gangosa, and that he had been the first American to describe it as an entity on the island of Guam. In order to correct the misapprehension that syphilis did not exist on that island, Dr. Arnold said that during his short service there he had seen a native hospital attendant with distinct mucous patches, and subsequently he had found the native woman who had caused this man's infection.

NOTES ON CHRONIC ULCERS OF THE PHILIPPINES,

by Dr. George C. Shattuck, of Boston, Mass. This paper (which was read by title), gave the clinical notes and microscopical findings in 34 cases of chronic ulcerative processes occurring in patients who were all natives of the Philippines, with the exception of one, a Chinaman. Four different types of ulceration were studied. The first and second were not definitely diagnosed; they were probably infections *sui generis*. In the third type the weight of evidence was slightly in favor of syphilis. Many examples of this type were seen. In the fourth type the probability of syphilis was strong. The remaining cases of the series seemed to be variations of types three and four, which might all be placed in one group. Together, they would comprise 94% of the series (32 cases). The diagnoses were all made clinically, because microscopic findings were all negative or ambiguous. The cellular content of the exudate examined was nearly the same in all the cases. The same was true of the bacteria seen. Blastomycetes were found in the exudate of 2 cases, but were not proved to be of etiological importance. Spirocheta refringens and two other varieties of spirochetæ were observed, but they were not believed to bear a causal relationship to the ulcers. Evidence of division was seen among the spirochetæ. The view that spirocheta refringens was a bacterium was supported by strong evidence of transverse division.

FILARIASIS,

by DR. T. TANAKA, of Tokyo, Japan. (Read by title).

(*a*) TROPICAL FORMS OF PITYRIASIS VERSICOLOR. (*b*) FRAMBESIA TROPICA (YAWS). ITS ETIOLOGY, CLINICAL SYMPTOMS AND TREATMENT. (*c*) OBSERVATIONS ON TINEA IMBRICATA. (*d*) OBSERVATIONS ON A PECULIAR DERMATOMYCOSIS,

by DR. ALDO CASTELLANI, of Colombo, Ceylon. (Read by title.)

A DEMONSTRATION OF THE USES OF LIQUID AIR IN DERMATOLOGY,

by DR. CHARLES T. DADE, of New York.

Book Reviews.

The Practitioner's Visiting List. 1908. Philadelphia and New York: Lea Brothers & Co.

This visiting list is now in its twenty-second year of issue. Those who have used it hitherto appreciate its merits. It has been, as usual, revised and brought up to date. It needs no further recommendation.

The Physician's Visiting List (Lindsay & Blakiston's) *for 1908.* Fifty-seventh year of its publication. Philadelphia: P. Blakiston's Son & Co. 1907.

The Medical Record Visiting List or Physicians' Diary for 1908. New revised edition. New York: William Wood & Co. 1907.

These two visiting lists are familiar and always useful. They appear in essentially the same form year after year, and evidently meet the needs of the physicians for whose use they are particularly prepared. The list prepared by P. Blakiston's Son & Co. is somewhat smaller than that of Wood & Co., and does not contain quite so much information as the latter. We recommend them both to our readers, as we have frequently done before. Some such list is indispensable for the active practitioner who desires to be systematic in his work.

The Operating Room and the Patient. By RUSSELL S. FOWLER, M.D., Professor of Surgery, Brooklyn Post-Graduate Medical School; Chief Surgeon, First Division, German Hospital; Surgeon, Methodist Episcopal Hospital, Brooklyn, N. Y. Second edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company. 1907.

Fowler's valuable book of 284 pages is an admirable supplement to the *Petite Chirurgie* on which we have commented below. He discourses upon the operating room, the preparation of the patient, the care of instruments, dressings and ligatures, the preparation of the surgeon and his assistants; and, most important of all, perhaps, he gives us six admirably concise chapters on the after-treatment of wounds and special infections. The book should be read by surgical assistants, hospital superintendents and operating nurses. It is full of useful hints for the country surgeon also.

Petite Chirurgie et Pratiques Spéciales Courantes. Par P. SOUBEYRAN, Professeur Agrégé a le faculté de médecine de Montpellier; et P. ARDIN-DELTEIL, Professeur de Clinique Médicale a l'école de Médecine d'Alger; avec 326 figures dans le texte. Montpellier: Coulet et Fils, éditeurs. Paris: Masson et Cie., éditeurs. 1908.

This little book of 400 pages on minor surgery is distinctly refreshing, not because the authors have anything especially new to tell us, but because their method of presentation is novel, and the illustrations of the text are graphic and admirable. The book begins with various chapters on technic, — not altogether satisfactory perhaps to American surgeons; for example, the use of rubber gloves is not commended. Then follow a series of chapters dealing in extensive detail with simple matters, generally slighted, with methods of giving injections of all sorts, with the removal of foreign bodies, with instructions on the proper handling of instruments, on tapping, on lumbar puncture, on gastric lavage, on fistula, minor gynecology and the use of sounds and catheters. On page 347 there is an illustration of horror, — a penis equipped with a permanent drainage catheter, tied in by means of a string fastened tightly about the glans. In spite of its occasional absurdities and shortcomings, however, the book is extremely useful and suggestive. Again we commend to American writers the capital and accurate outline-drawings with which the pages abound.

The Treatment of Fractures; with Notes upon a Few Common Dislocations. By CHARLES LOCKE SCUDDER, M.D., Surgeon to the Massachusetts General Hospital; Lecturer on Surgery in the Harvard University Medical School. Sixth edition, thoroughly revised and enlarged; with 856 illustrations. Philadelphia and London: W. B. Saunders Company. 1907.

The publishers inform us that over "twenty-five thousand copies of this remarkable work have been sold." Certain it is that Scudder's useful book holds a foremost place as a manual of treatment, and this sixth edition is an improvement upon its predecessors. It is larger; it embraces the treatment of dislocations as well as of fractures. The author adds to his previous writing a number of excellent and concise statements regarding the wisdom of operating upon certain fractures; he calls especial attention also to skull fractures in the newborn, to fractures of the bones of the face, and to fractures of the radius, the neck of the femur, and the carpal scaphoid; to unreduced dislocations of the elbow, to acromioclavicular dislocations, to pathological fractures, to old fractures of the radius, to Volkmann's contracture; and adds an important section on the treatment of ununited fractures. Again we admire the excellent work of the publishers, and again we commend this book to the profession.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 26, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 Boylston Street, Boston, Mass.

INFECTION FROM FLIES.

We have, from time to time, commented on the active crusade being taken in many quarters, first, to discover the dangerous attributes of the common fly, and, secondly, to devise adequate means of extermination. The prevalence of the fly during the summer is such that every possible opportunity is afforded for the propagation of infection and all the disaster to which this may lead. The extermination of the mosquito is relatively a simple matter as contrasted with that of the ubiquitous fly, but the latter must certainly be attempted if the present indications of its danger in the spread of infectious disease is substantiated. In this connection an important report has recently been made public in New York, to which we are glad to draw attention.

The Committee on Pollution of the Waters of New York of the Merchants' Association has sent to Governor Hughes an interesting and suggestive statement on infection from flies, which was prepared by Dr. Daniel D. Jackson, bacteriologist to the committee. The report was commended to the Governor's careful attention by Edward Hatch, Jr., chairman of the committee, among the other members of which are J. Pierpont Morgan and Dr. Albert Vander Veer. During the past summer and through the month of September, flies were collected each day from flytraps, at the piers all along the water-front of the city, and systematic examinations of these were made in Dr. Jackson's laboratory. At the same time, a careful investigation into the sanitary condition of the entire water-front was made. The results showed that the flies were thickest in number at the points where there was the most sewage, and where there was but little sewage there were few flies. Flies examined early in the season were found to carry less bacteria than in the heated time. The largest number of bacteria found in a single instance was 100,000, which were carried by a fly caught at a South Street pier on the East River in the hot weather. To just what extent the intestinal diseases prevalent in the summer season may be due to flies is a question not very easy to determine, but, at all events, the report shows that the mortality from these diseases "rose above the normal at the same time at which the flies became prevalent, culminated at the same high point, and fell off with a slight lag at the time of the gradual falling off of the prevalence of the insects." That flies are largely responsible is claimed in the report, which goes on to say that this so-called harmless insect is one of the chief sources of the infection, which in New York City causes annually about 650 deaths from typhoid fever and about 7,000 deaths from other intestinal diseases. The fall rise in typhoid, if set back two months from the report of deaths to the time of the contraction of the disease, would, it states, correspond exactly to the curve of prevalence of flies and to the curve of rise in deaths from intestinal diseases of both children and adults. "It also corresponds to the temperature curve. We are, therefore, erroneously inclined to view the disease as due to hot weather. While climatic conditions, by reducing the vitality, favor the contraction of the disease, they are not the real cause of it. Temperature does not produce the specific which invariably accompanies the disease. The activity of the house-fly is in proportion to the temperature, and the time at which it is most active and most numerous corresponds exactly with the time of the contraction of typhoid fever and other intestinal diseases."

THE REGISTRATION OF OPTICIANS.

A bill for the registration of opticians, which is to be introduced into the legislature this winter, has been mailed to every medical practitioner in the Commonwealth, accompanied by a very artfully worded circular asking for the support of medical men. A communication in another column of this issue of the Journal gives the history of the movement and should be read by

physicians before giving a hasty decision on the questions propounded in the circular.

It strikes us as, in reality, an attempt to acquire a quasi-medical registration under which opticians can advertise to cure headaches and other nervous disabilities. Under this bill, these gentlemen do not ask to be registered as opticians, but as "optometrists." Apparently, it is not the purpose of this board of opticians, if established, to examine applicants as to their knowledge of the manufacture of lenses and the proper fitting of the frames, but in regard to their ability to conduct examinations of the eyes of persons suffering from ocular defects. It is, we fear, the attempt of another group of that great body of men, who are always hovering about the outskirts of medicine, to gain a legal right to practise medicine without a medical education.

In this instance, they ask to be registered; and one of the provisions of the act is to give the board of registration the right to issue a certificate of proficiency over its common seal. Undoubtedly the seal, when affixed to the "optometrist's" diploma, will be large and have the arms of the Commonwealth of Massachusetts prominently emblazoned thereon. The lengths to which these gentlemen are prone to proceed was exemplified, not long ago, in a state in which an act of registration has, unfortunately, been enacted, when a duly registered optician publicly took to task the municipal authorities because they had had the examination of the eyes of certain school children conducted by oculists, stating that they should have called in "optometrists" who were licensed by the state to do such work, and were the only proper persons to make such examinations.

It would seem that specialization in medicine is producing new and dangerous classes of quasi-medical practitioners who advertise themselves as specialists. These men now wish to induce the state to legalize their practice of medicine without passing the medical board. We have seen a certain group of masseurs develop themselves into the "osteopaths"; now come the opticians, as "optometrists." Next may come the gentlemen who make and sell foot-plates, dubbing themselves with a new Latin or Greek name. After them, doubtless, the individuals who advertise facial massage and scalp treatment with another newly coined name, beginning with "derm," in all probability, and so on. The final result might be that a large part of the field of medicine would be covered by duly licensed and registered practitioners, all without a medical qualification.

REPORT OF THE CAROLINE BREWER CROFT FUND CANCER COMMISSION.

THE fourth report of the Caroline Brewer Croft Fund Cancer Commission of the Harvard Medical School is in our hands. The first report of this commission was issued in 1900, and during the seven intervening years, a large amount of experimental work has been done by various investigators, much of which has of necessity been a repetition of experiments previously published, particularly in relation to the parasitic origin of cancer. The general attitude of this commission in regard to the parasitic theory is well known. In its opinion it remains unproved. The commission is now under the direction of Dr. E. E. Tyzzer, of the Harvard Medical School, and the three papers presented in this report are the result of his researches. They are concerned especially with the question of inoculable tumors in mice. This work has been carried out in very great detail and is set forth with admirable photographic reproductions of the pathological conditions developing in the animals studied. In the introduction to this fourth report, Dr. J. Collins Warren, chairman of the commission, expresses the hope that the general investigation of cancer will in the future be carried on in a much more comprehensive way than has hitherto been done, and that endowments may be made to bring the clinical and laboratory work into closer relation than has hitherto been possible. In fact, the commission goes so far as to say that the investigation of cancer has now reached a point when it should be taken up on lines even broader than those laid down for the study and prevention of tuberculosis. Enough has certainly been done up to this time to show how difficult and elusive the problem is, and how much preliminary work of a negative sort must be done before positive advances toward the comprehension of the real nature of cancer and its causative agencies can be made. It is certainly to be hoped that sufficient funds may be forthcoming to render possible the most exhaustive work leading toward a solution of the problem.

MEDICAL NOTES.

AMERICAN JOURNAL OF UROLOGY. — Beginning with January, the above journal, which will also embrace venereal and skin diseases, passes under the editorial management of Dr. William J. Robinson, of New York.

Bequests. — By the will of the late Miss Zela Gibbs, of Newport, N. Y., St. Luke's Hospital in New York receives $100,000, and the residue of the estate after other bequests are paid. The Orthopedic Dispensary and Hospital receives $25,000.

Lord Kelvin to be Interred in Westminster Abbey. — It is proposed that the body of Lord Kelvin be interred in Westminster Abbey. But four other men of science have been hitherto so honored, — Newton, Herschel, Darwin, and Lyell.

A Worthy Record of Descendants. — A woman by the name of Ann Winn has recently died at the age of eighty-nine, near Falmouth, leaving 151 descendants. She herself had 17 children, the eldest of whom is now seventy-one. There are 75 grandchildren and 59 great-grandchildren. The woman's husband was a blacksmith, and it is said she often assisted him with bellows and hammer.

A Presidential Possibility. — An "underground movement" is said to be on foot "to boom" Attorney-General Bonaparte for President. The campaign managers are said to be physicians, and the issue the "extermination of the criminal classes." The medical profession and the proposed candidate are supposed to agree on the desirability of segregating habitual criminals. A further platform is not stated.

Deaths in Coal Mines. — Recent statistics show that during the last seventeen years, 22,840 men have been killed in the mines of this country. During the last six years as many fatalities have occurred as during the preceding eleven years. In 1906, 6,861 men were killed or injured, and the record this year bids fair to surpass any previously made. It is worthy of mention that three times as many are killed in this country as in most of the European countries to each 1,000 employed.

Death of Dr. William Bayard. — The death is announced of Dr. William Bayard, a practitioner of medicine in St. John, New Brunswick, for seventy years. Dr. Bayard continued in active practice almost up to the end of his life of ninety-four years. He was graduated from Edinburgh University in 1837, and quickly took a prominent place in various departments of medical work in St. John, where he began his practice. In 1895 he was president of the Canadian Medical Society. Last August, the seventieth anniversary of Dr. Bayard's graduation, Edinburgh University conferred upon him the degree of LL.D. He was then supposed to be the oldest living graduate.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Dec. 25, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 58, scarlatina 47, typhoid fever 3, measles 26, tuberculosis 60, smallpox 0.

The death-rate of the reported deaths for the week ending Dec. 25, 1907, was 24.64.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Dec. 21, 1907, was 283, against 210 the corresponding week of last year, showing an increase of 67 deaths and making the death-rate for the week 24.22. Of this number 146 were males and 137 were females; 275 were white and 8 colored; 172 were born in the United States, 104 in foreign countries and 7 unknown; 60 were of American parentage, 178 of foreign parentage and 45 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 51 cases and 1 death; scarlatina, 35 cases and 1 death; typhoid fever, 1 case and 1 death; measles, 34 cases and 0 deaths; tuberculosis, 57 cases and 16 deaths; smallpox, 1 case and 0 deaths. The deaths from pneumonia were 60, whooping cough 0, heart disease 27, bronchitis 9 and marasmus 3. There were 15 deaths from violent causes. The number of children who died under one year was 54; the number under five years 71. The number of persons who died over sixty years of age was 91. The deaths in public institutions were 72.

There were 8 cases and 4 deaths reported from cerebrospinal meningitis during the week. There were also 11 deaths reported from la grippe.

The Diagnosis of Malaria and Typhoid Fever in Connecticut. — The Connecticut State Board of Health announces to physicians and health officers of that state that its laboratory is now prepared to undertake the diagnosis of malaria, and outfits for this work are now in the hands of the health officers and may be obtained by physicians wishing to make use of them. In using these outfits, physicians are requested to follow the directions accurately, since the diag-

nosis of malaria is difficult, and is impossible unless the specimen sent is prepared carefully.

The laboratory is beginning the use of a new style of typhoid outfit which it is believed will give more accurate results. The new outfits are being gradually substituted for the older style, and health officers are requested to furnish the new style of outfit to physicians instead of the old style, when they have them.

NEW YORK.

TRAVELING TUBERCULOSIS EXHIBIT. — The New York State Charities Association is maintaining a traveling tuberculosis exhibit which is being sent to various cities and towns throughout the state. It has just been employed at a successful two weeks' campaign in Utica, where a committee on the prevention of tuberculosis has been organized and free dispensary for consumptives established.

NEW YORK ACADEMY OF SCIENCES. — The annual meeting of the New York Academy of Sciences was held on Dec. 16, when Charles F. Cox was elected president, and Dr. Adolf Meyer, director of the pathological institute of the New York state hospitals, one of the three vice-presidents. The meeting was followed by the annual dinner, after which the retiring president, Dr. N. L. Britton, made an address on the organization and construction of the New York Botanical Garden in Bronx Park, of which he is at present the director.

ACCIDENTS FROM PUBLIC CONVEYANCES. — The reports filed with the Public Service Commission show that during the months of September, October and November, no less than 155 persons were killed and 500 seriously injured in New York City by the street cars, and steam, elevated and subway trains. Prior to the inauguration by the Public Service Commission, which was created by the last legislature, of its system of accident reports, there was no adequate way of determining the number of persons killed or injured within the city limits by the different traction lines, but these companies are now required to file reports of all accidents with the commission.

TYPHOID FEVER AT TRENTON, N. J. — The epidemic of typhoid fever, now prevailing at Trenton, N. J., seems to be unquestionably due to the use of Delaware River water. Up to Dec. 15, fifty-five cases had been reported during the present month, and Dr. A. C. Hunt, chief sanitary officer of the State Board of Health, has expressed the fear that worse is to come unless existing conditions are quickly remedied. The State Health Department has repeatedly warned the city against such an epidemic, but it appears that the expense of construction has proved too much of an obstruction to the installation of a filtration plant by the board of water supply. There is now some talk of obtaining a permanent supply of pure water from the Sorrell Mountains, to be conveyed by means of an aqueduct, but, of course, such a project would necessarily require a very considerable time to carry out.

DEATHS FROM INFLUENZA. — The present year will show a greater mortality from influenza than any year since 1891, when in the city of New York, then comprising the present boroughs of Manhattan and the Bronx, the number of deaths from this cause, reached 854. The second highest mortality was in 1895, amounting to 567, while the lowest record was in the year 1902, when there were only 102 deaths reported from influenza. In the first eleven months of 1907, there were 509 deaths in Manhattan and the Bronx, as against 200 in the corresponding period in 1906, or an increase of more than 150%. During the first two weeks of December, the death-rate from influenza was even proportionately larger; so that the record of 1907 will undoubtedly exceed that of 1895. In all the large hospitals, there are now many influenza patients, while an unusually large number of those suffering from the disease in less severe form are receiving treatment in their out-patient departments, and in the various dispensaries.

Obituary.

HENRY PATTERSON LOOMIS, M.D.

DR. HENRY PATTERSON LOOMIS, of New York, the only son of the late Prof. Alfred L. Loomis, died from pneumonia, after a short illness, on Dec. 22, in the forty-ninth year of his age. He was born in New York City, where he prepared for college, and in 1880 he was graduated from Princeton. In 1883 he received the degree of M.D. from the medical department of the University of the city of New York, and, after serving as interne at Bellevue Hospital, he studied abroad for two years, taking special courses at the universities of Heidelberg and Vienna. On his return he became associated in practice with his father, and later was appointed professor of pathology in the New York University medical school. He was also made visiting physician to Bellevue Hospital, and in 1896 visiting physician to the New York Hospital, both of which posi-

tions he retained up to the time of his death. When the new Cornell University Medical College was organized in 1898 he became a member of the faculty as professor of Materia Medica, Therapeutics and Clinical Medicine, and this professorship he also still occupied at the time of his death. The distinguished son of an eminent father, Dr. Loomis was recognized as one of the leading pathologists and exponents of internal medicine in New York, and his frequent contributions to medical literature were of a high order. One of the most notable of these was a paper which he read in a symposium on pneumonia in December, 1905, before the Medical Association of the Greater City of New York, which was participated in by Drs. Hobart A. Hare, James M. Anders and J. Madison Taylor, of Philadelphia, and Drs. Andrew H. Smith, William H. Thomson and others, of New York. In this he presented a *résumé*, very carefully prepared in minute detail, from original sources, of the existing treatment of lobar pneumonia as exemplified by the routine treatment of the disease in four of the large New York hospitals. The hospitals taken for comparison were Bellevue, the New York, the Presbyterian and Roosevelt, the material collected showing an enormous amount of painstaking work on Dr. Loomis's part, and in concluding the paper he gave some practical deductions which clinical experience seemed to warrant as regards the treatment of pneumonia. Dr. Loomis was a man of most genial temperament, beloved by his associates and patients, and always very popular with his classes, and it seems sad indeed that he should thus be cut off in his prime and at the height of his useful medical career. His wife was Miss Julia Stimson, a sister of the distinguished surgeon, Dr. Lewis A. Stimson, and she, with two children, a son and daughter, survive him. The son, Alfred L. Loomis, is now a sophomore at Yale.

1. Saxe was able to find either skins, sago bodies, or sugar granules after prostatic massage in the urine of 12 out of 26 young men, whose seminal vesicles and prostate were apparently normal, and who presented no evidence of venereal infection, either from the history or physical examination. The presence of vesicular casts does not of itself indicate inflammation, unless they contain pus cells and bacteria. The casts arise from stagnation of the secretion of the vesicles, with consequent absorption of the fluid portion, and indicate only atony of the vesicular walls. Vesicular shreds with pus, epithelium and many spermatozoa occur in chronic vesiculitis. The diagnosis of vesiculitis is only possible by finding pus cells, vesicular epithelia, spermatozoa and bacteria. The latter are usually streptococci, less frequently gonococci, occasionally staphylococci and colon-like bacilli.

7. Berkeley frankly confesses that the proof of specific relation between Parkinson's disease and the parathyroid gland is quite inadequate. Autopsy findings are, on the whole, against such a relation, although the parathyroid seemed pathological in a few cases. Such a relation is suggested by the symptoms in animals after complete parathyroid excision, *viz.*, twitching of the voluntary muscles, tetany and convulsions. The writer has employed preparations from the parathyroid glands of the ox, both by mouth and subcutaneously, in some 75 cases of Parkinson's disease. Eighteen of the 30 cases which were followed were progressively benefited, some apparently remarkably so. The benefit consisted in diminished rigidity, pain, salivation and shaking, relief of restlessness and insomnia, and greatly increased voluntary control of muscles. The writer promises a further report in collaboration with S. P. Beebe.

3. Freeman finds that heating of milk for forty minutes at 140° F. (60° C.) does not interfere with its biologic properties or chemical composition, and also kills the bulk of the bacteria, including the tubercle bacillus.

6. Kilmer reports a series of 550 cases of whooping-cough treated by the abdominal belt. These cases represent the observations of some thirty pediatricians. Most of the observers testified to the almost constant benefit noticed regarding the cessation of vomiting and moderation of cough. It is in no sense a curative procedure. The belt is made of linen with a strip of silk elastic webbing two inches wide inserted in either side. The belt laces in the back and is worn over the undershirt. The width is

four to eight inches, depending on the size of the child. The length is about three inches less than the circumference of the child's abdomen at the navel. At first, only slight constriction is used, which is increased until the vomiting is controlled. [R. I. L.]

1. Billings describes the symptoms and signs of motor insufficiency of the stomach due to atony or to pyloric obstruction, or, as the title of his paper indicates, to perigastric and duodenal adhesions. These adhesions are most often due to cholecystitis, less often to chronic ulcer or to operations. The condition may be masked by symptoms of the underlying cholelithiasis or ulcer; it is to be detected by signs of stasis in the stomach contents in the absence of evidence of ulcer. Neurotic symptoms are often present. One case is described at length in which the diagnosis was made and the condition relieved by operation, with temporary improvement. Neurotic symptoms, however, recurred without objective signs of abnormal gastric function.

3. Moffitt reports a case of frequently recurring attacks of fever for a year or more, finally fatal. Autopsy proved the presence of lymphosarcoma of the liver, spleen and lymph glands. Attention is called to the frequent occurrence of fever in tuberculous lymphomas, in Hodgkin's disease, sarcoma and carcinoma. As other causes of obscure intermittent fevers, are mentioned pyelitis, endocarditis, intermittent hepatic fever, visceral syphilis, tuberculosis and exophthalmic goiter.

4. "Intestinal dyspepsia" Einhorn defines as including all conditions in which the digestive function of the intestinal tract is disturbed. Two main classes of cases are described: "Dyspepsia intestinalis universalis," in which digestion of all three classes of food substances is at fault; and "dyspepsia intestinalis partialis," divided into subclasses, when digestion of only one or two forms of food is disturbed. In preference to Schmidt's test diet, the author uses his own "bead test," giving beads containing meat, fat, fish-bone, thymus, potato and catgut, and examining their contents when they are recovered from the stool. Cases are cited, illustrating the conditions described and method of diagnosis. As to treatment, the patient is put on a liquid or semi-liquid diet, and pancreon or takadiastase (gr. v, t. i. d.) is given, the former to promote digestion of proteids or fats, and the latter in amylaceous dyspepsia.

5. Schmoll's article is an attempt to show that in paroxysmal tachycardia we have to deal not with a single pathological entity, but with at least four groups as follows: (1) cases in previously damaged hearts; (2) cases from dysthyreosis; (3) cases with lesions of the central nervous system; and (4) cases of apparently functional character. The condition is characterized by attacks of suddenly appearing tachycardia, lasting ten or fifteen minutes up to five days, ceasing as suddenly as they began. In the attack the heart rate is either double or four times the normal. Cases are described showing how these features may occur in connection with each of the etiological factors mentioned. Most attention is directed toward the so-called idiopathic or functional cases. These were carefully studied by means of tracings, in the attempt to explain the occurrence of the increased heart rate upon physiological grounds. Through these tracings it is made evident that the tachycardia is the result of extra systoles, in some instances apparently originating in the bundle of His and involving only the ventricle, and in other instances, by the presence of an auricular wave, more probably originating in the venous sinus.

10. Riesman mentions a number of manifestations of tendency to hemorrhage occurring in connection with Bright's disease. These include epistaxis, purpura, metrorrhagia, hemoptysis, hematemesis, hematuria and bleeding into the brain, eye and ear. In a few cases, hemorrhage has occurred from multiple sources, indicating a true hemorrhagic diathesis. The author favors the view that the nephritis is the cause of the tendency to hemorrhage, most probably by toxic influence, possibly aided by arterial disease and hypertension. The prognosis in these hemorrhagic cases is unfavorable.

12. Schorer reports results of treatment of 37 cases of erysipelas by means of injections of killed cultures of streptococci. The organisms were obtained from cases of erysipelas, but it was not feasible to use, in each case, organisms obtained from that case. The technic is briefly described and results are summarized and tabulated. In general the outcome was inconclusive. The opsonic index was found excessively variable and of no value as an indication of the severity of the disease. The injection of killed streptococci, on the whole, increased the opsonic index, but no corresponding improvement of the patient was observable. [F. W. P.]

2. Jackson believes tonsillotomy an unjustifiable operation: first, because it leaves parts of the gland as a seat for future infections and inflammations whose adequate drainage is prevented by scar-tissue; second, because it severs vessels at a point where disease process hinders their normal retraction and makes hemorrhage more likely than after tonsillectomy. The best treatment for post-operative tonsillar hemorrhage he thinks to be direct torsion of the bleeding point with a hemostat, applied while the anterior pillar is fully retracted. If this fails, he recommends immediate external carotid ligation.

7. Primary intraligamentous fibroids, not connected with the uterus, are rare. Vance reports a case of his own, and summarizes others from the literature. The condition is rarely bilateral, and may be associated with uterine fibroids, in which case the diagnosis cannot be made before operation. When the uterus is not also involved, the absence of menstrual disturbance is an important diag-

nostic sign. Fibroid of the broad ligament may easily be mistaken for ovarian cyst, especially since it is very liable to cystic degeneration.

10. Careful analysis of 100 cases of cancer of the penis seems to show that phimosis is the predominant predisposing cause, being present in 85% of the series. Jews are notably immune. These facts, Barney believes, are strong arguments for prophylactic circumcision, when phimosis persists after middle life. The progress of the disease is relatively slow, the prognosis, after early radical operation, relatively good, 38% of all cases being cured. Amputation does not necessarily destroy sexual power or cause disturbance of micturition.

11. Andrews modifies Jaboulay's eversion method for radical cure of hydrocele by making only a 2 cm. incision into the funicular portion of the sac. Upon delivery of the testicle, this incision contracts about the cord, leaving the sac inside out, and secure in position without need of suture, except for closure of the scrotal wound.

14. The use of balsam of Peru as a primary dressing in lacerated wounds of all varieties and extent is reported, apparently with gratifying results, which Suter attributes to mechanical, bactericidal and direct chemotactic action of the drug. The urine should be watched for evidence of absorptive irritation of the kidneys.

8. SCHUMM, O. *The Benzedin Blood Test.*

2. Riedel discusses 130 personal cases of displaced right kidney fastened by adhesions in abnormal positions. Only 7 of these were in men. The clinical pictures were those usually described. If there was a tumor present, it was due to an exacerbation of a hydronephrosis which, if infected, caused fever and albuminuria; if not, the urine was normal. This is similar to the action of the gall bladder when distended and stones present. In other cases, violent pains and vomiting may suddenly develop, without fever or changes in the urine, due to adhesions about a displaced kidney. The liver is displaced in one half the cases, often occupying the normal position of the kidney. Tight skirt bands, when worn without corsets, he thinks are liable to cause these displacements. The varying position of the adhesions caused varying clinical pictures. The appendix may be constricted or adhesions may develop to the liver or anterior abdominal wall. In some cases, apparently insignificant adhesions caused uncontrollable vomiting and abdominal colic. He states that he does not know of any operation that is so beneficial in its results as that of fixation of a displaced kidney fastened by adhesions. In simple wandering kidney he does not advise operation.

4. Ribbert briefly reviews the modern theories of how the tubercle bacillus gains its entry into the body, and criticises the views of Aufrecht and others who maintain that the primary infection is usually hematogenous, with a portal of entry in the tonsils or mouth. He reaffirms his own conviction that inhalation is the chief source of infection in man.

5. Pal states that the observation of Schur and Wiesel that the serum of nephritis contains mydriatic substances induced him to carry out similar experiments with the urine of patients suffering from various affections The test was carried out on the enucleated eye of the frog Eighty-one cases in all were tested. The reaction was not present in any of the normal cases; it was present in 78% of the cases of nephritis and in 7% of the cases of other diseases, and in 33% of 18 cases of pregnancy. The question is to be investigated further, and the author suggests that the mydriatic action may be due to the excretion of adrenalin.

7. Heymann reports the results obtained in the treatment of various skin diseases by means of the quartz lamp as compared with the Finsen lamp, or its modifications. He concludes that it is more convenient to manipulate, less expensive, requires smaller amounts of current, and easily causes deep necroses that are slow to heal.

1. Baumgarten has made a large number of observations on animals after subcutaneous injections of alcohol. No local necrosis or abscess formation was found at the point of injection. Further, no formation of new connective tissue in the liver or elsewhere was noted. He did find, in many cases, erosions of the mucous membrane of the stomach and intestines. From these experiments, the author suggests that alcohol is not a causal, but a predisposing, factor in cirrhosis of the liver in man.

3. Beck reports 5 cases in which, after removal of malignant new growths, the operation site was subjected to vigorous x-ray treatment until inflammatory reaction set in. In these cases there has been no return of the tumor. The author believes that in all cases of infiltrating new growths of skin or subcutaneous tissues, the above procedure is a most valuable one.

4. Witte describes the Solms-Jakoby method of pepsin estimation. A mixture of $\frac{n}{10}$ HCl and sodium chloride ricin solution is used as a test fluid; it is milky in appearance. When mixed with fluids containing pepsin, the milky precipitate is dissolved. The gastric juice to be tested is mixed with the test fluid in different dilutions in separate test-tubes, 1: 50, 1: 100, etc., depending on the amount of free HCl present. After three hours in the incubator the tubes are examined, and the greatest dilution tube in which the precipitate has cleared is taken as the one showing the pepsin content. The author finds a relation in all cases between the amount of HCl and the amount of pepsin, but it is not a constant one. His results differ from many observers, in that he finds a diminution of the pepsin content in cases of functional disturbances of the stomach, as well as in organic disease. This method is simple, cheap and accurate, and can be performed by the practitioner.

2. *CITRON, J. *Serum Diagnosis of Syphilis.*
3. EINHORN, M. *The Diagnosis and Treatment of Ileus.*
4. KERSTEN. *A Case of Congenital Stricture of the Ileum.*
5. SCHRÖDER, K. *The Guaiac Test for Blood.*
6. BORSE, B. *Arthritis and Its Relation to Venereal Disease.* (Continued article.)
7. *DIESLING. *The Significance of Pigment in Malaria.*

2. Citron finds it possible to recognize antibodies in the serum of nearly every syphilitic, no matter what stage of the disease is present. Also in 80% of paretics, the antibodies are demonstrable in the spinal fluid. The author believes that the presence of such antibodies means an active syphilitic process, and that their absence may be interpreted as evidence of cure or latency. The increase in the reaction is an indication for further anti-specific treatment. He concludes from his observations that, firstly, the longer the toxin of syphilis has affected the

body, and the more numerous the relapses it has caused, in so much is the antibody content of the serum more constant and more marked; secondly, the earlier the mercury treatment has been instituted, and the longer it has been applied, by so much is the antibody content lessened.

7. Diesling claims that quinin acts by combining with the hemoglobin of the red cells, and that this combination is visible through the microscope. The clinical course of malaria may be watched and predicted by observations on the pigment excretion in urine and feces. The life cycle of the parasite depends on the absorption and assimilation of pigment. The author points out that many substances have great influence on the hemoglobin combinations, and that for a successful treatment of the disease, it only remains to select such substances that do not have a hurtful influence on the human organism.

REVUE DE CHIRURGIE.
NOVEMBER, 1907.

1. *FRENCH CONGRESS OF SURGERY. (*Twentieth Session Held at Paris, Oct. 7–12, 1907.*)
2. *PROCEEDINGS OF THE THIRTY-SIXTH CONGRESS OF THE GERMAN SOCIETY OF SURGERY. (*Held at Berlin, April 3–6, 1907.*)

1. X-ray treatment of malignant disease is believed by Béclère to be of great value, especially for epitheliomata of the face. His optimism is questioned in the discussion, but supported by Imbert and Dupeyrac, who report 80% of cures in cutaneous cancer. Pozzi recommends the use of high frequency sparks, which he thinks preferable to x-ray in all accessible forms of malignant disease. The dangers of over-exposure to x-ray are emphasized, and in general radiotherapy is deemed of secondary value to surgery, except in cancer of the face. Its use is advised, however, in inoperable cases and as a means of preventing recurrence following operation, though several disapprove of leaving open, for the latter purpose, wounds that might otherwise be closed.

Reports and discussion of nerve, muscle and tendon transplantation in the treatment of paralyses add little to our present knowledge and practice on the subject.

The relation of trauma to malignant neoplasm and local tuberculosis is considered, with the conclusion that though a single injury may call attention to or accentuate the development of a previously existing lesion, or afford the site for a direct inoculation of tuberculosis, it is rarely the immediate occasion of malignant or tuberculous disease, and even then cannot be called an etiologic cause. Sarcoma follows trauma more commonly than does cancer. These considerations are of obvious medico-legal importance in expert testimony in damage suits.

2. Reports on progress in thoracic surgery emphasize the value of the pneumatic chamber. By operating under a negative pressure of 3 mm. of mercury, Sauerbruch found that suture of the heart for trauma could be done with less hemorrhage and greater ease, on account of cardiac quiescence. Friedrich employs a negative pressure of 3 to 8 mm for all intra-thoracic procedures to avoid pneumothorax. Seidel, on the contrary, when pneumothorax already exists, employs a slight positive pressure to prevent the establishment of atelectasis.

[R. M. G.]

Exploratory Puncture of the Brain. Neisser's brain puncture constitutes an important advance in the diagnosis of certain diseases of the brain and its membranes. POLLACK (*Mitt. a. d. Grenzg. d. Med. u. Chir.*, Bd. 18, Heft 1, p. 1) reports further results obtained with this method in Neisser's clinic, and reviews the literature. The skull and soft parts are rapidly punctured under local anesthesia, by means of a small electric drill. The exploratory needle is introduced through this opening and aspiration is performed at any desired distance from the inner surface of the skull. The procedure is not accompanied by shock or unpleasant after-effects, provided that the rules laid down by Neisser and Pollack (*same journal*, Bd. 13, p. 807) are followed. The puncture can be repeated, if necessary, several times in different places at one sitting. By this method, it is possible to localize brain tumors and abscesses accurately, and thus needless trephining may be avoided. In inoperable brain tumors, by puncture of the lateral ventricles, the symptoms of pressure may be relieved often more efficaciously than by decompression operations, and the method has not the danger attendant on lumbar puncture in such cases. The latter, as is well known, may entirely fail to relieve the pressure symptoms, owing to a blocking off of the communication between the cerebral and spinal cavities, and has, moreover, been followed by sudden death in quite a few instances. In cases of extradural hemorrhage, it is sometimes impossible to tell by the usual methods on which side of the head the lesion is, and life is sometimes lost by trephining on the wrong side. The exploratory brain puncture in such cases is invaluable, and may, as in the case reported by the author, suffice to effect a cure after the aspiration of the blood. It is to be hoped that this method will receive a more general trial than it has yet had.

Correspondence.

LETTER FROM PARIS.

(From our Special Correspondent.)

ASCENDING AND DESCENDING PROCESSES.

PARIS, Dec. 10, 1907.

Mr. Editor: I must own up to being rather partial to an iconoclast, especially to one who is thoroughly convinced, and makes a clean sweep of things He is apt to be a young man, who, finding that the ground has been pretty well gleaned by his predecessors, and that entirely new ideas are scarce, realizes that, in order to come to the front, he must resolutely overthrow by force some portion of the already existing order of things.

So he walks boldly into your lot, makes disparaging remarks about the shanty in which you have lived so long and been quite content, and finally, with a vigorous shove, sends the entire edifice to the ground. After which he invites you to step over into his lot to see how far superior the building he has just put up is to the ruined structure you have left behind.

This sort of treatment is the best possible mental gymnastics for the man who is beginning to get on in life. There is no better test for the elasticity and activity of the protoplasmic prolongations of his big pyramidal cells than, just when they have comfortably settled down into ruts, and have become accustomed to certain modes of action and to ideas following each other in a well-known sequence, to be obliged at a moment's notice, not only to adopt an entirely new habit of life, but to completely shake off the old one as well,— not always the easiest matter in the world!

Osler says somewhere, that "it is a horrible thought, but very true, that we reach a stage in life, some earlier, some later, in which a new truth, a perfectly obvious truth, cannot be accepted." Well, so far as I am personally concerned, it is a satisfaction to me to find that in this respect I am all right, for the present, at any rate. For I am quite prepared to accept the following revolutionary doctrines, if they prove capable of clinical demonstration; they are, to say the least, very attractive.

Two young iconoclasts over here, former internes, Lemierre and Abrami, have recently advanced the following new ideas as regards the biliary complications of typhoid fever, — at least so they have seemed to me.

Not so very long ago, most people held that typhoid fever was due to a microbe that gained access to the intestine with the ingesta, that multiplied therein with great facility and that set up, first, local catarrh with inflammation of Peyer's patches, and, later on, systemic infection and intoxication. In the cases in which the disease was accompanied or followed by catarrhal or inflammatory disturbances of the passages of the bile and gall bladder, these accidents were held to be due to an *ascending* infective process from the intestine, occurring when the composition of the bile or the facility of its flow was not in a normal state.

These conceptions seemed to be rational; they held together fairly well, and everybody was satisfied.

But on closer scrutiny some features were brought to light that rather jarred in the tableau. Thus, the characteristic lesions of the intestine in typhoid fever are found at the lower end of the ileum, far away from the bile apparatus, in the neighborhood of which the mucosa is usually in a perfectly normal state. This detail did not seem to fit in well with the idea of an ascending infection. Again, the urine was discovered to be swarming with Eberth's bacilli, eliminated by the kidneys. Now there could be no question of any ascending infection here, the bacilli being brought to the renal filter by the circulation. Furthermore, it was ascertained that at post-mortems after typhoid fever, the bile in the vesicle is filled with Eberth's bacilli in a state of pure culture, although there had been no clinical signs of cholangitis or cholecystitis, and although the vesicle and ducts were macroscopically perfectly healthy. Doubts then began to arise as to the soundness of our belief that typhoid fever was an intestinal affair, an enteritis; and on different sides experimentors set to work to study this question of the presence of these bacilli in the bile.

With the progress of microscopic technic, an important discovery was soon made: that from the start of the disease, the specific bacilli can be demonstrated in abundance in the circulation. This at once changed the entire aspect of affairs, and the theory was advanced that the disease is primarily a septicemic process and not an enteritis!

If, now, we apply this idea to what we know of typhoid fever, we must interpret its phenomena as follows: the bacilli, arriving with the ingesta, penetrate at once into the circulation and there begin to multiply. Reaching the liver and kidneys with the blood they are eliminated in the urine and bile, in the latter of which, an excellent culture medium, they increase rapidly in numbers. In most cases their presence in these liquids is quite silent; in a few they give rise to cystitis, or cholecystitis, the two processes being of exactly the same nature, being both *descending* lesions and no longer ascending, in the case of the bile passages.

The intestinal endanthema, on this theory, is not due to the presence and direct action on the mucosa of the bacilli, but is a localized metastasis of the Eberth septicemia. Typhoid fever is, then, no more an intestinal disease than variola is a cutaneous one, — the external eruption of the one and the intestinal patches of the other being neither the seat of the virus nor the essense of the disease. Lastly, with this interpretation of the disease, the bacilli that can be demonstrated in the stools came from hepatic elimination and multiplication, and not from intestinal culture.

It is certainly trying to the ordinary mortal to have his venerable beliefs knocked about in this ruthless fashion. It all seemed so plausible: the ascending infection of the bile passages, like surgical urinary infection from bladder to kidney, or sexual infection from urethra to testicle; and yet, it cannot be gainsaid that the new theory appeals to the mind strongly. Furthermore, it has been demonstrated beyond doubt, experimentally, that bacilli can easily pass from the circulatory current into the bile. Incidentally, it may be remarked that this idea of *descending* infection may upset the entire chapter of the diseases of the bile passages; so that our troubles with this obscure region of the economy are not yet approaching an end, by any manner of means!

"Spectator."

P. S. As the true physician should be eclectic, and be on the lookout for good things, no matter how humble their origin, I send the following therapeutic tip just received in a letter from a London hospital-trained nurse, now serving in Johannesburg, South Africa:

"A Boer woman in my ward gave birth to twins, one of which had slight jaundice. She told me she had always given her babies *lice* as a remedy for this, three being the dose for an infant and ten for an adult, between two slices of bread and butter. In reply to my question as to where she got them, she answered that the Kaffir servant always supplied them, either off his body or out of his hair."

This somewhat enables one to rise to the height of grasping the tales of horror related by the English physicians who had to serve among the Boer women and children in the concentration camps, during the South African war, in explanation of the fearful mortality among the Boer sick!

WALKING AND HEALTH.

Boston, Dec. 23, 1907.

Mr. Editor: The excellent editorial, "Walking and Health," which appeared in your issue of Dec. 12, calls deserved attention to a subject of importance. Weston's extraordinary walk at the age of sixty-nine is of all the greater value from a medical standpoint, because it was done under normal and natural conditions. Most records in athletics are created and often under abnormal conditions; but Weston wore ordinary clothes and walked over ordinary country roads, the cinder track and racing costume being conspicuous by its absence. It was, therefore, a performance which with practice may be imitated though not equalled by both sexes and all ages.

Two aspects of this extraordinary walk deserve particular attention; in the first place, it demonstrates the heretofore incredible possibilities of the physical powers of what is ordinarily considered old age; it sets a new final standard of these possibilities which recalls in some particulars the demonstration of the new minimum physiological diet which Chittenden has recently given to physiologists; both of these new standards overturn others which had been established and accepted for years. Unless one has tried to walk more than forty miles in a single day under favorable conditions it is not possible to fully appreciate what it means to average 50 miles on a series of successive days under unfavorable conditions. The fact that it can be done and without serious harm should encourage all healthy folk to extend their mental picture of their walking powers. For us in Boston, our superb park system and the attractive surrounding country invite the walker to unusual delights; they should be more extensively appreciated and utilized; without doubt, for us, walking is the simplest, the most enjoyable, the most easily available form of general exercise for the conservation of health. The automobile and the electric car must not be allowed to banish it.

A second aspect of walking is its great possibility as a therapeutic agent in convalescence from sickness, surgical operations and debilitated or neurasthenic conditions of all sorts.

It must, however, be more carefully considered and prescribed; in a word, more accurately administered than has heretofore been the case. A comparison is suggested between the use of water as carried out at medical baths, and walking as it might be practiced in the open air: the careful consideration of temperature, force, character of the application of the water in one case corresponds to the speed, duration, distance and character of the country to be covered by the walk. Viewed from this standpoint, walking offers almost unlimited possibilities to the patient. It is the modern custom to discharge surgical patients from our hospitals at an early date, before returning to their occupations, which are often tedious and arduous; something more than simple rest is desirable. Walking can fill this place more effectively and acceptably than the usual artificial exercises. This is particularly true in the case of abdominal scars, and operations for the relief of hernia. Carefully considered, walking is ideal for strengthening such scars, and accustoming them gradually to the strains which they must ultimately bear. It is also valuable as an immediate treatment of sprains of a moderate degree, as Weston himself demonstrated; it is better than most forms of formal gymnastics and "setting up" drills, for children and adults with weak backs, round shoulders and flabby muscles generally. Finally as a means of severe physical exercise it may be combined with climbing on the one hand and running on the other, to both of which it is intimately related; it may be utilized to produce the maximum exertion which can be demanded within physiological limits. Let us hope that it will be utilized more extensively in these various ways.

Truly yours,

J. B. Blake, M.D.

RECORD OF MORTALITY

APPOINTMENTS.

FREDERICK H. VERHOEFF, M.D., has been appointed instructor in Ophthalmic Pathology at the Harvard Medical School.

RICHARD DEXTER, M.D., has been appointed an assistant in Clinical Medicine at the Harvard Medical School.

NATHANIEL R. MASON, M.D., has been appointed an assistant in Obstetrics and Gynecology at the Harvard Medical School.

EXAMINATION.

PHYSICIAN (MALE). INDIAN SERVICE. — The United States Civil Service Commission announces an examination on Jan. 15, 1908, at certain designated places, to secure eligibles from which to make certification to fill vacancies as they may occur in the position of physician (male) in the Indian Service, at salaries ranging from $720 to $1,200 per annum.

Seven hours will be allowed for this examination.

Age limit, twenty-five to fifty-five years on the date of the examination.

Men only will be admitted to this examination.

This examination is open to all citizens of the United States who comply with the requirements.

Applicants should at once apply to the United States Civil Service Commission, Washington, D. C.

SOCIETY NOTICES.

THE NORFOLK DISTRICT MEDICAL SOCIETY. — A meeting for scientific improvement will be held at Masonic Temple, 171 Warren Street, Roxbury, on Tuesday evening, Dec. 31, 1907, at 8 o'clock. Practical questions concerning mental diseases: Emergency Cases of Mental Disease, Responsibility of the Physician Called, Sources of information, Dr. William Noyes. Conditions Likely to be Mistaken for Insanity, Dr. Edward B. Lane. Some Forms of Insanity Likely to be Overlooked, Dr. Miner H. A. Evans. Some Borderline Considerations, Dr. Daniel H. Fuller. The discussion will be opened by Dr. H. R. Stedman, Dr. C. G. Dewey, Dr. L. A. Roberts. Light refreshments will be served. WILLIAM H. ROBEY, JR., *Secretary.*

A PROPOSED NEW ENGLAND PEDIATRIC SOCIETY. — The Visiting Staff of the Boston Floating Hospital request all those interested in the formation of a New England Pediatric Society to meet at the Boston Medical Library, 8, The Fenway, Saturday, Jan. 4, 1908, at 8.15 P.M. It is hoped that this movement will excite general interest and that the attendance at the meeting will not be limited to those working along this special line.

JOHN LOVETT MORSE, *Chairman.*
WILLIAM E. FAY.
ARTHUR WILLARD FAIRBANKS.
CHARLES W. TOWNSEND.
HENRY I. BOWDITCH, *Secretary.*

RECENT DEATHS.

DR. W. WALTON WOOLSEY WINTHROP, a descendant of Governor John Winthrop, of Massachusetts, died in New York on Dec. 21. He served as a surgeon for two years in the Civil War, and after that spent most of his time in traveling. He made many trips around the world, and was well known in London and Paris, where for years he made his headquarters.

DR. JOSEPH EVERETT GARLAND, M.M.S.S., one of the most prominent physicians in Eastern Massachusetts, died in Gloucester, Dec. 16, 1907, aged fifty-six years, where he has practiced for many years. On the day of his funeral the schools were closed and flags on public buildings were placed at half mast.

DR. CHARLES H. BAILEY, a prominent practitioner of Bloomfield, N. J., died on Dec. 18, from cerebral apoplexy. He was a son of the Hon. Alexander Hamilton Bailey, of Utica, N. Y., who succeeded Roscoe Conkling as a member of Congress from that district when Mr. Conkling was elected to the United States Senate. As a young man he served in the Civil War. He studied medicine in Geneva and New York, and was graduated from the College of Physicians and Surgeons, New York. When the Mountainside Hospital at Montclair was organized, twenty years ago, he became one of the attending surgeons, a position which he retained up to the time of his death, and for many years he was president of the medical board of the hospital. He also served at one time as president of the local board of health. He had practiced in Bloomfield for thirty-seven years.

DR. SAMUEL PRESTON CROPPER, of New York, died, after a long illness, on Dec. 19. He was sixty years of age, and was graduated from the College of Physicians and Surgeons, New York, in 1877.

ELMER ELLSWORTH GOODWIN, M.D., M.M.S.S., died in Haverhill, Dec. 18, 1907, aged forty-two years.

BOOKS AND PAMPHLETS RECEIVED.
